Abstract

I build a novel model to study how volatility shocks to firm-level productivity affect unemployment through the financial channel of wage commitments. My model can explain 90% of the increase in unemployment during the Great Recession, twice the magnitude in [Schaal \(2017\)](#). The key idea is that wage bills are debt-like commitments by firms to workers, which firms are less likely to take on when volatility is high, so firms hire fewer workers and unemployment increases. The model's performance in explaining unemployment deteriorates greatly if either financial frictions or volatility shocks are absent. Given the model's quantitative success, I use it to analyze the impact of the United States and German labor market policies during the recent Covid recession. The U.S. policy raises unemployment benefits, making it more expensive for firms to pay wages, amplifying the recession. Germany subsidizes firms' wage bills but yields little impact because it requires cutting workers' hours, which is costly for firms to bear the output loss and apply for the subsidy.

Keywords: search and matching, financial frictions, volatility shocks, firm heterogeneity, business cycles.

1 Introduction

Motivated by the work of [Bloom et al. \(2018\)](#), among others, there is now a large literature that finds that volatility¹ shocks can rationalize the business cycle dynamics of several key macroeconomic variables, including output, investment, and employment.² One exception, though, is *unemployment*: [Schaal \(2017\)](#) shows that a canonical search model with volatility shocks can only generate 40% of the increase in unemployment during the Great Recession, even though volatility increased a lot in that period. In this paper, I build on [Schaal's \(2017\)](#) analysis by adding firm financial frictions to his baseline paradigm.³ I show that this augmented model can explain 90% of the increase in unemployment during the Great Recession.

The economics of this dramatic improvement in model performance are intuitive. In my search model, firms and workers agree to labor contracts that are incomplete in the sense, so future wages cannot change in response to changes in productivity.⁴ The wage contracts operate like debt commitments – specifically, if a firm cannot honor its promised wage payment ex-post, it has to default and its operations are liquidated. Hence, wage bills are like debt commitments of firms to workers. Firms are less likely to take on these commitments by hiring when volatility is high. In this way, aggregate increases in firm volatility translate into higher unemployment.

The model needs both market incompleteness and volatility shocks to generate sufficient unemployment volatility. Market incompleteness means firms can only borrow through state-uncontingent debt contracts, and they cannot use labor contracts to hedge idiosyncratic productivity risks, either.⁵ Therefore, firms' idiosyncratic risks can lead to financial distress and thus discourage hiring. Furthermore, volatility shocks increase the degree of idiosyncratic risks sharply during recessions ([Bloom et al., 2018](#)) and thus can quantitatively generate sizable unemployment fluctuations.

Given its quantitative success, I use the model to analyze the impact of American and German labor market policies during the recent Covid recession, which also features sharply rising volatil-

¹ By “volatility”, I mean the conditional (cross-sectional) variance of firm-level productivity.

² Papers that point out the crucial role of volatility shocks over business cycles include [Basu and Bundick \(2017\)](#), [Bloom et al. \(2018\)](#), [Christiano, Motto and Rostagno \(2014\)](#), [Fajgelbaum, Schaal and Taschereau-Dumouchel \(2017\)](#), and [Fernández-Villaverde et al. \(2011\)](#).

³ See [Alfaro, Bloom and Lin \(2019\)](#), [Arellano, Bai and Kehoe \(2019\)](#), [Gilchrist, Sim and Zakrajšek \(2014\)](#), etc., for earlier studies of the joint effects of firm financial frictions and volatility shocks on other macroeconomic variables.

⁴ They can change in response to variation in the worker's outside option.

⁵ Specifically, I assume that lifetime promised utility equals the worker's outside value plus a state-uncontingent markup. Firms can choose a utility markup, but the markup is restricted to be the same across tomorrow's states. In other words, the labor contract is not a complete financial instrument but resembles state-uncontingent debt. Notice that both incompleteness in the financial and labor markets are necessary. Otherwise, firms can easily hedge against risks when either the debt contract or labor contract is complete.

ity.⁶ In the United States, the Federal Pandemic Unemployment Compensation (FPUC) program increased unemployment benefits during Covid. My model suggests that a 1% increase in unemployment benefits when volatility is high increases unemployment by an additional 5%. Higher unemployment benefits push up wages, make employment riskier for firms, and thus amplify the negative impact of volatility.

On the other hand, Germany subsidized firms to pay wages and maintain employment. Although this policy does reduce firms' financial concerns about making wage commitments, the model predicts that it does not yield a significant stabilization effect. First, this policy is quite expensive. The policy required cutting workers' hours to get the subsidy, resulting in output loss, so it is costly for firms to apply for it. Second, firms anticipate that the policy of wage subsidies will be implemented during volatile periods. Hence, firms tend to hire more workers in advance, causing a slump in labor demand after the volatility shock hits.

Building on [Schaal \(2017\)](#), my model is new because of the additional financial channel. Two papers have brought financial frictions to [Schaal's \(2017\)](#) model ([Blanco and Navarro, 2016](#); [Sepahsalari, 2016](#)).⁷ The biggest challenge is modeling long-term employment relationships and financial constraints at the same time. When the distribution of employees' contracts becomes one of the state variables, the problem is not computationally tractable. To circumvent this issue, they assume that wages do not enter firms' financial constraints, so wages are pure internal transfers. Thus, they can solve the problem of the firm and its employees jointly without needing to track the distribution of contracts. Unlike those papers assuming firms have deep pockets to pay wages, I assume that wage contracts are incomplete, so wages are part of the firm's financial concern. My model is still computational tractable because I follow the implicit contract literature assuming that firms are committed to labor contracts while workers are not. So, the promise-keeping and participation constraints help me endogenously pin down wages. Therefore, I also do not need to track the distribution of employees' contracts and preserve computational tractability.

Because they are incomplete, wage contracts can trigger inefficient separations. This is exactly how debt contracts are modeled in the financial frictions literature ([Arellano, Bai and Kehoe,](#)

⁶ Using the US monthly panel Survey of Business Uncertainty (SBU) and the UK monthly Decision Maker Panel (DMP), [Altig et al. \(2020\)](#) show that business executives are much more uncertain about their firms' future sales growth rates during the COVID-19 pandemic.

⁷ Earlier papers also put financial frictions into search models, including [Boz, Durdu and Li \(2015\)](#), [Christiano, Trabandt and Walentin \(2011\)](#), [Chugh \(2013\)](#), [Eckstein, Setty and Weiss \(2019\)](#), [Garin \(2015\)](#), [Mumtaz and Zanetti \(2016\)](#), [Petrosky-Nadeau \(2014\)](#), [Schoefer \(2021\)](#), [Wasmer and Weil \(2004\)](#), [Zanetti \(2019\)](#), and so on. People also relate search models to the asset pricing literature, e.g., [Hall \(2017\)](#) points out the effect of discount rates on unemployment, and [Kehoe et al. \(2022\)](#) leverage human capital accumulation and preference shocks to generate unemployment volatility. However, to the best of my knowledge, they need to assume homogeneous firms, one-worker firms, constant returns to scale, or i.i.d. idiosyncratic productivity for computational tractability. These assumptions are unsuitable for studying volatility shocks to firm-level productivity and firms' intensive hiring decisions. Thanks to [Kaas and Kircher \(2015\)](#) and [Schaal \(2017\)](#) for providing the block-recursivity ([Menzio and Shi, 2010, 2011](#)) for firms with decreasing-returns-to-scale production functions, I can build on their models to add financial frictions and study how volatility shocks affect firms' hiring while keeping the computational tractability.

2019; Khan and Thomas, 2013; Ottonello and Winberry, 2020). Supporting evidence for inefficient separations caused by incomplete wage contracts can be found in Jäger, Schoefer and Zweimüller (2019). They use a quasi-experimental repeal of an unemployment insurance extension in Austria and find that surviving jobs do not display higher resilience. Therefore, they conclude that those separated jobs are not simply the ones with the lowest surplus, and separations are thus not efficient in the data. Although they use this evidence to support wage rigidity, my assumption of incomplete wage contracts also has similar implications. On the other hand, recent papers show that firms do not have deep pockets to pay wages. Instead, Favilukis, Lin and Zhao (2020) point out that wage growth and labor shares are the primary predictors of credit spreads, Donangelo et al. (2019) show that firms with higher labor shares are more sensitive to shocks, and Schoefer (2021) finds that higher labor share industries display greater cash flow cyclicalities.

An important finding related to Shimer's (2005) puzzle is that unemployment is very responsive to volatility shocks under my mechanism, relative to productivity shocks. My full-fledged model can explain 90% of unemployment volatility in the data. When the aggregate productivity shock is the only aggregate shock in the model, the recalibrated model produces only 65% of unemployment volatility. This number is similar to the case without financial frictions at all.⁸ Although a negative aggregate productivity shock can also push firms into difficult financial conditions, my model suggests that the effect is weak because wages fall a lot, which greatly reduces the negative impact of the aggregate productivity shock. This is also the reason for Shimer's (2005) unemployment volatility puzzle, i.e., that a standard Diamond-Mortensen-Pissarides search model generates far less unemployment volatility than in the data because of the offsetting effect of wages.

On the other hand, this offsetting effect of equilibrium wages is much weaker for volatility shocks. Since the production function is decreasing returns to scale, profits are convex with respect to idiosyncratic productivity. A volatility shock spreads the productivity distribution and pushes up the firm's value, i.e., the Oi-Hartman-Abel effect (Oi (1961), Hartman (1972), and Abel (1983)). As a result, wages do not need to decrease much to satisfy the free entry condition. Volatility shocks are correspondingly less subject to the offsetting response of wages than aggregate productivity shocks. Therefore, unlike a typical search model with only aggregate productivity shocks and homogeneous firms, my results suggest that the volatility shock is crucial to understanding unemployment dynamics because firms have limited ability to hedge idiosyncratic risks.

Related Literature. First, my paper complements the literature on the effect of volatility shocks

⁸ Different from Shimer (2005), aggregate productivity shocks alone in my model can generate a great portion of unemployment volatility, consistent with Schaal (2017). The reason is that modeling heterogeneous multi-work firms amplify unemployment volatility, as pointed out by Hawkins (2011).

over business cycles.⁹ [Schaal \(2017\)](#) investigates how volatility shocks affect unemployment in a search framework. In his model, volatility shocks cannot generate a sufficient increase in unemployment during the Great Recession, primarily because his calibration indicates small search frictions in the US labor market. My work builds on [Schaal \(2017\)](#) by considering the financial channel of wage commitments, which substantially improves the model’s performance in explaining unemployment.

The addition of a financial channel via wage commitments is motivated by several papers emphasizing how financial frictions modify the effect of volatility shocks, most closely [Arellano, Bai and Kehoe \(2019\)](#), who use risky hiring and volatility shocks to explain the slump in output and employment during the Great Recession. However, they focus on a competitive labor market where employment fluctuations reflect leisure choice. Instead, I study unemployment caused by search frictions. [Christiano, Motto and Rostagno \(2014\)](#) consider volatility shocks in the financial accelerator model of [Bernanke, Gertler and Gilchrist \(1999\)](#), showing that fluctuations in volatility are able to drive more than 60 percent of output changes over business cycles. [Gilchrist, Sim and Zakrajšek \(2014\)](#) emphasize a large negative impact of volatility shocks on investment, mainly through the increase in credit spreads. [Alfaro, Bloom and Lin \(2019\)](#) provides empirical evidence that financially constrained firms are more negatively affected by volatility shocks in terms of investment. A common feature of these papers is that they abstract from unemployment. My work complements these studies by using a search framework to understand the effect of volatility shocks on unemployment.

Second, my work contributes to recent papers studying the effect of incumbent workers’ wages on unemployment by proposing a new mechanism of wage commitments. In most search models, what matters for hiring is the present value of a match. In other words, given the present value, how incumbent workers’ wages are paid is irrelevant for unemployment volatility. Three recent papers use different mechanisms reflecting incumbent workers’ wage rigidity to break this theoretical paradigm. [Bils, Chang and Kim \(2022\)](#) assumes varying working efforts. [Schoefer \(2021\)](#) uses firms’ borrowing constraints. [Rudanko \(2019\)](#) impose within-firm wage equity constraints. [Fukui \(2020\)](#) leverages on-the-job search and wage posting to generate wage stickiness endogenously. My work complements theirs by providing another mechanism—firms’ future wage commitments. Unlike a story of sticky wages, my model’s main driving force is that firms cannot use incomplete labor contracts to hedge against idiosyncratic shocks. My quantitative results show that this mechanism, together with volatility shocks, greatly improves the model’s performance in explaining unemployment fluctuations.

⁹ Volatility in my paper specifically refers to micro-level volatility, i.e., the volatility of firm-level idiosyncratic productivity documented by [Bloom et al. \(2018\)](#). As for the macro-level volatility of aggregate productivity shocks, [Leduc and Liu \(2016\)](#) and [Freund and Rendahl \(2020\)](#) use homogeneous-agent models to study the interaction of nominal rigidity and macro-level volatility on unemployment. [Den Haan, Freund and Rendahl \(2021\)](#) emphasizes the real option channel of macro-level volatility due to search frictions. Due to computational burden, my paper does not include macro-level volatility, supported by [Schaal \(2017\)](#), who argues that the size and impact of macro-level volatility shocks are small.

Layout. The paper proceeds as follows. I first set up the model in Section 2. Section 3 calibrates the model and presents the results of business cycles and policy experiments. Section 4 concludes.

2 Model

To study the impact of aggregate shocks on unemployment, I build a directed search and matching model. The equilibrium is block recursive to provide tractability, following [Menzio and Shi \(2010, 2011\)](#), [Kaa and Kircher \(2015\)](#), and [Schaal \(2017\)](#).¹⁰ The model also features financial frictions with firm default risks, following [Arellano, Bai and Kehoe \(2019\)](#).

2.1 Environment and Timing

There are four types of agents in the economy: workers, firms, managers, and international financial intermediaries. Workers are infinitely lived and risk-neutral. They have the same productivity. The total mass of workers is normalized to one unit. Firms are also risk-neutral. They hire workers to produce homogeneous goods and finance by borrowing from the financial intermediaries.

Firms' idiosyncratic productivity is drawn from the Markov process $\pi_z(z'|z, \sigma)$, where σ is the aggregate volatility shock to the economy. Higher volatility implies a more widely spread distribution of tomorrow's idiosyncratic productivity shocks, so firms are more likely to draw a low idiosyncratic productivity. The other aggregate shock in the economy is the aggregate productivity shock A . I use S to summarize the two aggregate shocks (A, σ) . Firms also face an i.i.d. random operating cost shock ϵ , which follows a normal distribution $\Phi_\epsilon \equiv \mathcal{N}(\mu_\epsilon, \sigma_\epsilon^2)$. I use s to denote the two firm-specific shocks (z, ϵ) .

I assume that job search is directed. Each labor submarket is indexed by a promised utility x , which is the lifetime utility firms promise to workers hired from this submarket. The submarket tightness θ is the ratio of vacancies to the number of workers looking for jobs in each submarket. I use $p(\theta)$ to denote the job-finding rate of workers and $q(\theta)$ to denote the vacancy-filling rate of firms. The relation between x and θ will be determined by the free entry condition in equilibrium.

Following the implicit contract literature, I assume that firms are committed to labor contracts while workers are not. So, workers can leave the firm whenever their outside option is better. One justification for this approach is that firms care about their reputations more than individual workers. I denote the recursive-from labor contract as $C = \{w, \tau, W'(S', s'), d(S', s')\}$, where w is the current wage payment, τ is the layoff probability, $W'(S', s')$ is the next-period employment value promised by the firm, and $d(S', s')$ is the indicator for the firm's exit decision.

¹⁰ As for other search models with multi-worker firms, [Acemoglu and Hawkins \(2014\)](#) and [Elsby and Michaels \(2013\)](#) introduce Nash bargaining into random search. Because my paper focuses on business cycles, I leverage directed search with block recursivity to solve the problem globally out of the steady-state.

Figure 1: Timing

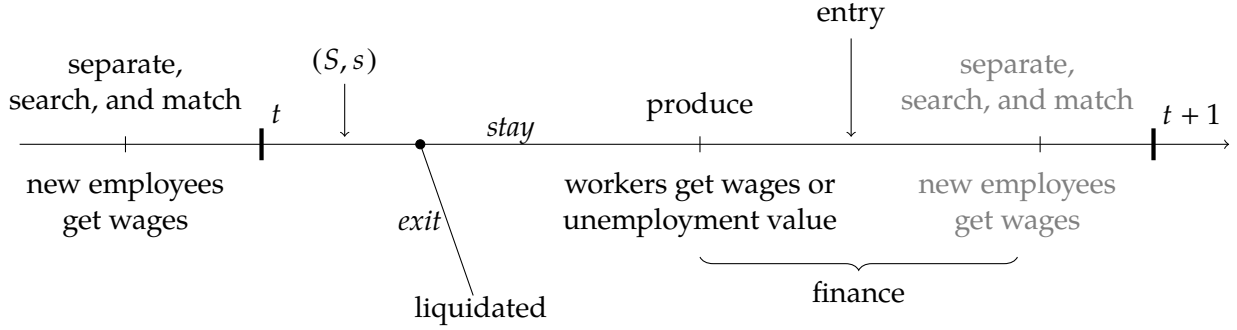

Figure 1 shows the timing. At the end of the preceding period, firms and workers interacted in the labor market to separate, search, and match. They draw up labor contracts in this stage. And newly employed workers receive wages. At the beginning of the current period, all shocks (S, s) realize. Then firms decide to exit or not. If a firm exits, it defaults on all its debts, including labor contracts, and its operations are liquidated. Otherwise, firms produce based on the number of employees as determined at the end of the last period. At the same time, employed workers receive wages according to continuing labor contracts. Unemployed workers also obtain unemployment benefits in this stage. Next, potential new firms can pay an entry cost to enter, after which both new entrants and incumbent firms participate simultaneously in the labor market. Firms borrow from international financial intermediaries to finance the expenditure during the process.

2.2 Worker's Problem

There are two types of workers in the economy: unemployed and employed workers. I abstract from the participation margin.

Unemployed Worker's Problem. An unemployed worker receives unemployment benefits \bar{u} in the current period and chooses a submarket x_u to job search to maximize their unemployment value. The matching probability $p(\theta(S, x_u))$ depends on the aggregate shocks and the promised utility of the submarket. Therefore, the unemployment value is:

$$U(S) = \max_{x_u} \bar{u} + p(\theta(S, x_u))x_u + (1 - p(\theta(S, x_u)))\beta \mathbb{E}U(S'). \quad (1)$$

Employed Worker's Problem. The value of employment depends on the contingent labor contract $C = \{w, \tau, W'(S', s'), d(S', s')\}$. The worker receives his wage w in the current period and can simultaneously search for other jobs as well. I use x to denote his choice of on-the-job search submarket. If he successfully gets a new job, he receives x as lifetime utility. Notice that the job finding rate $p(\theta(S, x))$ is discounted by the relative on-the-job search efficiency λ , which matches the job-to-job transition rate.

In the next period, if the worker is laid off or the firm exits, he will be unemployed and receive the unemployment value $U(S')$. Otherwise, he can still work for the firm and receive the promised utility $W'(S', s')$. Notice that I assume firms are fully committed to labor contracts, but workers are not. Therefore, for promised utilities lower than the unemployment value, the worker will voluntarily leave the job and become unemployed. The following equation formalizes the value of employment:

$$\begin{aligned} W(S, s, C) = & \max_x w + \lambda p(\theta(S, x))x \\ & + (1 - \lambda p(\theta(S, x)))\beta \mathbb{E} \left\{ [\tau + (1 - \tau)(\pi_d + (1 - \pi_d)d(S', s'))]U(S') \right. \\ & \left. + (1 - \tau)(1 - \pi_d)(1 - d(S', s')) \max\{W'(S', s'), U(S')\} \right\}. \end{aligned} \quad (2)$$

where π_d is the exogenous exit rate of firms.

2.3 Firm's Problem

Firms maximize their present values, namely, the discounted cumulative sum of equity payouts.

A firm's states include realized aggregate shocks $S \in \mathcal{S}$, realized firm-specific shocks $s \in \mathcal{s}$, the number of employees n , and the set of promised utilities to its employees $\{W(S, s; i)\}_{i \in [0, n]}$, where i is the index of incumbent employees within the firm.

Firms optimize over the current equity payout Δ , next-period debt b' , next-period employment n' , the number of workers to hire n_h , the submarket x_h in which to search, and next-period exit decisions $d(S', s')$. I assume that a firm only posts vacancies in one submarket each period. Firms also choose the current-period wages of incumbent workers $w(i)$, the layoff probability $\tau(i)$, the wages of newly hired workers $w_h(i')$, and the set of next-period lifetime utilities $\{W(S', s'; i')\}_{S' \in \mathcal{S}', s' \in \mathcal{s}'; i' \in [0, n']}$, subject to the participation constraint (8) and the promise-keeping constraint (9). I use $w(i)$ for incumbent employee i 's wage, \bar{w}_m for the manager's wage¹¹, and $w_h(i')$ for the wage of a newly hired employee i' .

Equations (3) to (11) summarize the firm's problem starting from the production stage:

$$\begin{aligned} J(S, s, b, n, \{W(S, s; i)\}_{i \in [0, n]}) = & \max_{\substack{\Delta, b', n', n_h, x_h, d(S', s'), \\ \{w(i), \tau(i)\}_{i \in [0, n]}, \\ \{w_h(i')\}_{i' \in (n' - n_h, n']}, \\ \{W'(S', s'; i'), \bar{W}(i')\}_{S' \in \mathcal{S}', s' \in \mathcal{s}'; i' \in [0, n']}}} \Delta \\ & + \beta(1 - \pi_d) \mathbb{E}_{S', s' | S, s} \left\{ (1 - d(S', s')) J(S', s', b', n', \{W(S', s'; i')\}_{S' \in \mathcal{S}', s' \in \mathcal{s}'; i' \in [0, n']}) \right\} \end{aligned} \quad (3)$$

¹¹ One manager per firm.

$$\text{s.t. } \Delta = Azn^\alpha - \int_0^n w(i)di - \bar{w}_m - \epsilon - b - c \frac{n_h}{q(\theta(S, x_h))} - \int_{n'-n_h}^{n'} w_h(i')di' + Q(S, z, b', n')b' \geq 0, \quad (4)$$

$$n' = \int_0^n (1 - \tau(i))(1 - \lambda p(\theta(S, x^*(S))))di + n_h, \quad (5)$$

$$x^*(S) = \arg \max_x p(\theta(S, x))[x - \beta \mathbb{E} U(S')], \quad (6)$$

$$W'(S', s'; i') = U(S') + \bar{W}(i'), \quad (7)$$

$$\bar{W}(i') \geq 0, \quad (8)$$

$$\mathbf{W}(S, s, C) \geq \begin{cases} W(S, s, i) & \text{for } i \in [0, n], \\ x_h & \text{for newly hired employees,} \end{cases} \quad (9)$$

$$i'(i) = \int_0^i (1 - \tau(j))(1 - \lambda p(\theta(S, x^*(S))))dj, \forall i \in [0, n], \quad (10)$$

$$Q(S, z, b', n')b' - n_h \frac{c}{q(\theta(S, x_h))} - \int_{n'-n_h}^{n'} w_h(i')di' \geq M(S, z, n) - F_m(S, z), \quad (11)$$

$$\text{where } F_m(S, z) = \left[\frac{\bar{w}_m + (1-\lambda) \frac{\beta}{1-\beta} \bar{w}_m}{(1-\Phi(A\xi \mathbb{E}[A'z'n'^\alpha - \int_0^{n'} w(i')di' - \bar{w}_m - \epsilon'])\zeta \mathbb{E} z')} \right]^{\frac{1}{\alpha}} \bar{u}.$$

The firm chooses its equity payouts Δ for the current period. I assume that firms are subject to the non-negative equity payout constraint in equation (4). I adopt this assumption so that firms cannot always raise cash through equity issuance, which ensures financial frictions are effective in my model. Equity payouts Δ equal output Azn^α minus the wage payments to incumbent employees $\int_0^n w(i)di$, minus the manager's wage \bar{w}_m , minus the stochastic operating cost ϵ , minus debt b , minus vacancy posting costs $c \frac{n_h}{q(\theta(S, x_h))}$, minus wage payments to newly hired workers $\int_{n'-n_h}^{n'} w_h(i')di'$, and plus borrowings $Q(S, z, b', n')b'$. I assume that output is decreasing returns to scale with respect to the number of employees by letting α be smaller than one. This assumption helps generate meaningful firm sizes, essential to capturing firms' downsizing behaviors when subject to high volatility. The parameter c is the posting cost per vacancy. To hire n_h new workers, the firm needs to post $\frac{n_h}{q(\theta(S, x_h))}$ vacancies, where q denotes the vacancy-filling rate. The total vacancy posting cost is correspondingly $c \frac{n_h}{q(\theta(S, x_h))}$. The bond price Q is determined such that the international financial intermediaries break even, which will be defined later.

Equation (5) is the law of motion for employment. The firm's next-period number of employees is the sum of staying employees and new hires. Employees can separate from the firm for two reasons, on-the-job search and layoffs. Employees optimally choose an on-the-job search submarket to maximize their expected lifetime utility as in eq. (6). I use $x^*(S)$ to denote the optimal on-the-job search market. Then the probability for a worker to transit to another firm is $\lambda p(\theta(S, x^*(S)))$. If the worker does not find a new job, he faces a layoff probability $\tau(i)$. Therefore, eq. (5) means that

the staying employees plus new hires sum to the next-period employment.

Eq. (7) assumes a specific contract form for the next-period promised utilities, which are comprised of two parts: the outside option of unemployment $U(S')$ and a utility markup chosen by the firm $\bar{W}(i')$. The promised utility markup can be contingent on workers, but it does not vary across states. The state-uncontingency of $\bar{W}(i')$ is crucial for effective financial frictions. Suppose firms' future promises to workers could be contingent on states. Labor contracts will then serve as a much better financial instrument than state-uncontingent bonds, which I conceive of as a counterfactual. Appendix D uses asymmetric information to provide a micro-founded model to justify this setup. The idea is based on Hall and Lazear (1984), who prove the optimality of predetermined wages when considering information frictions. Specifically, suppose workers do not have information about the firm's conditions. Firms can lie to pay less to workers. Because workers do not know whether the firm is truly facing a bad shock, they will not accept the wage cut. Section 2.10 discusses the assumption of a state-uncontingent promised utility markup in detail.

Recall that I assume firms are committed to labor contracts, but workers are not. Therefore, the participation constraint (8) shows that the firm should promise a non-negative utility markup to retain its workers. Otherwise, the worker would rather be unemployed. Furthermore, the promise-keeping constraint (9) requires the firm to adhere to its commitment that the worker's employment value is at least the promised lifetime utility. For incumbent worker $i \in [0, n]$, his promised utility is $W(S, s, i)$, one of the firm's state variables. For a newly hired worker, his promised utility is x_h , according to the firm's choice of hiring submarket. Finally, eq. (10) formalizes the transition of the employee's index from i to i' .

The last constraint (11) reflects the agency frictions between shareholders and managers, following Jensen (1986) and Arellano, Bai and Kehoe (2019).¹² This constraint dampens the firm's saving incentives so that financial frictions are effective in the model. Otherwise, firms will build up a large cash buffer and never default.

The micro-foundation of the agency frictions is as follows. I assume that there is a pool of potential managers from which each firm can hire one manager to operate the firm. The total mass of managers is much smaller than of workers, so I abstract from managers when calculating unemployment. Each manager can also be self-employed and produce \bar{w}_m units of goods. The market for managers is competitive, so a manager's wage is also \bar{w}_m .

Each period consists of a day and night. During the day, managers are monitored by the firm's shareholders, so managers adopt the firm's optimal policies. The manager uses borrowing $Q(S, z, b', n')b'$ and sales to pay dividends, wages of incumbent workers, his own wage, the

¹² Workers own firms in the model, so they are shareholders. I do not explicitly model equity payouts in the worker's problem because workers are risk-neutral and the free entry condition implies that the firm's net present value is zero.

operating cost, and debt. Search happens overnight, and the manager is supposed to use the remaining resources to pay vacancy posting costs and the wages of new workers. However, what happens during the night cannot be observed by shareholders until the next day. Therefore, the manager can propose an alternative production plan to the financial intermediary to borrow as much as possible at night. To convince the financial intermediary of the new plan (\bar{b}', \bar{n}') , the manager needs to provide proof by posting vacancies to have \bar{n}' workers in the next period if hiring is necessary. The manager thus needs to pay vacancy posting costs and wages for newly hired workers for the alternative proposal. In sum, to maximize available funds, the manager will come up with a proposal to achieve maximum possible borrowing net of hiring costs:

$$M(S, z, n) = \max_{\substack{b', n', n_h, x_h, d(S', s'), \\ \{\tau(i)\}_{i \in [0, n]}, \{w_h(i')\}_{i' \in (n' - n_h, n']}, \\ \{W'(S', s'; i'), \bar{W}(i')\}_{S' \in S', s' \in s'; i' \in [0, n']}} Q(S, z, b', n')b' - n_h \frac{c}{q(\theta(S, x_h))} - \int_{n' - n_h}^{n'} w_h(i') di' \quad (12)$$

$$\text{s.t. (5), (7), (8), and (9).} \quad (13)$$

Given the maximum net borrowing $M(S, z, n)$, the remaining credit available for the manager is the maximum net borrowing minus the previous borrowing plus the originally planned but unused money for search, i.e., $M(S, z, n) - Q(S, z, b', n')b' + n_h \frac{c}{q(\theta(S, x_h))} + \int_{n' - n_h}^{n'} w_h(i') di'$.

The manager wants to use the remaining resources to hire workers to produce for his own project in the next period. After the next-period production occurs, shareholders learn what has occurred. The extra workers will be laid-off and search for jobs. Because the manager only needs to hire workers for the next-period production, the outside value of unemployment benefits \bar{u} is the lowest wage for the manager to retain workers to produce. The manager will use the rest of the funds to hire as many workers as possible. The number of workers n_s is determined by

$$n_s = \frac{M(S, z, n) - Q(S, z, b', n')b' + n_h \frac{c}{q(\theta(S, x_h))} + \int_{n' - n_h}^{n'} w_h(i') di'}{\bar{u}}. \quad (14)$$

The manager takes advantage of the firm's productivity for his sided project, so the output is

$$\zeta z' n_s^\alpha,$$

where ζ indicates the profitability of the manager's own project.

I also assume that there is an auditing technology to detect a manager's intention to deviate at night. The effectiveness of the auditing technology, ξA , is based on a measure of auditing quality, ξ , proportional to aggregate productivity. The incentive and available resources to use the auditing technology are approximated by the firm's expected income $\mathbb{E}[A' z' n'^\alpha - \int_0^{n'} w(i') di' - \bar{w}_m - \epsilon']$. The more the firm expects to earn, the more it can and should pay for the auditing technology.

I assume that the probability of the manager being caught is Gaussian and determined by the amount of auditing:

$$\Phi\left(\xi A \mathbb{E}[A' z' n'^\alpha - \int_0^{n'} w(i') di' - \bar{w}_m - \epsilon]\right). \quad (15)$$

I model the auditing technology to match the correlation between credit spreads and aggregate output, so the financial effect of aggregate productivity shocks is consistent with the empirical covariance. Otherwise, a positive aggregate productivity shock will cause counterfactually higher credit spreads because firms would have higher income and borrow substantially to avoid the managerial deviations. With the auditing technology, firms do not need to borrow that much when aggregate productivity is high, so the credit spreads decrease, as in the data.

Suppose the manager deviates from the firm's optimal policies and works on his side project. In that case, shareholders will find out and fire the manager the next day. Assume the manager faces probability λ of becoming self-employed (else returning to the manager market), which approximates the punishment for deviation. Therefore, to avoid manager deviations, the firm should not operate with significant unused credit so the manager cannot hire many workers and the side project is not attractive. To do so, the firm should satisfy the following constraint such that the manager prefers to be honest:

$$\left(1 - \Phi\left(\xi A \mathbb{E}[A' z' n'^\alpha - \int_0^{n'} w(i') di' - \bar{w}_m - \epsilon]\right)\right) \mathbb{E}_t \beta \zeta A_{t+1} z_{t+1} n_s^\alpha + \lambda \mathbb{E}_t \sum_{j=2}^{\infty} \beta^j \bar{w}_m \leq \mathbb{E}_t \sum_{j=1}^{\infty} \beta^j \bar{w}_m,$$

which delivers the agency friction constraint (11) by plugging in equation (14).

The agency friction constraint (11) incentivizes firms to borrow in the spirit of [Jensen \(1986\)](#). Without agency frictions, firms have strong incentives to save and grow out of financial frictions. There are other options to reduce firms' savings, such as using a lower discount factor. But the model requires an unrealistically low discount factor to match observed leverage since firms are very opposed to liquidation. For other ways to make firms borrow in the presence of financial frictions, [Quadrini \(2011\)](#) provides one summary.

2.4 Wages

The state of the firm's problem (3) is an infinite-dimensional object because of the set of promised utilities. This section shows how to simplify the firm's problem by deriving wages and default decisions.

First, the promise-keeping constraint (9) always binds. Otherwise, firms could lower wages and earn more. Moreover, Proposition 1 shows that the participation constraint (8) also binds.

Proposition 1 *The participation constraint (8) binds, i.e., $\bar{W}(i') = 0$, for any worker i' .*

Appendix C provides the proof. Here, I explain the intuition. The participation constraint (8) requires that the promised utility markup should be non-negative. Suppose there exists a strictly positive promised utility markup $\bar{W}(i') > 0$. Then the firm can have a relatively low current wage according to the binding promise-keeping constraint (9). Namely, a positive promised utility markup can be understood as borrowing from the employee by backloading wages. However, borrowing from employees is more costly than borrowing from lenders through bonds. The reason is that lenders only discount the firm's default probability, but employees also discount the layoff risks. Therefore, firms never want to backload wages and promise a positive utility markup.

Given the binding promise-keeping constraint (9) and the participation constraint (8), I am able to determine wages. The binding participation constraint (8) implies that the promised utilities always equal the unemployment value U . From the worker's problem (1) and (2) and the binding promise-keeping constraint (9), an incumbent worker's wage is

$$\begin{aligned} w(S) &= U(S) - \lambda \max_x p(\theta(S, x)) [x - \beta \mathbb{E} U(S')] - \beta \mathbb{E} U(S') \\ &= \bar{u} + (1 - \lambda) \max_x p(\theta(S, x)) [x - \beta \mathbb{E} U(S')]. \end{aligned} \quad (16)$$

That is, an incumbent worker's wage equals the outside payoff of being unemployed minus gains from on-the-job search.

Similarly, a newly hired worker's wage equals

$$w_h(S) = x_h - \beta \mathbb{E} U(S'). \quad (17)$$

The uniquely determined wages in (16) and (17) are crucial for solving the problem quantitatively. Given the wages, the infinite-dimensional distribution of promised utilities not informative as a state variable, and the firm's problem can be simplified by removing the implicit contract constraints, (7), (8), and (9).

In terms of employment, the following Lemma 2.1 shows that while the model pins down the firm's total layoffs, the individual worker's layoff probability is undetermined.

Lemma 2.1 *The firm's total layoffs $\int_0^n \tau(i) di$ is uniquely determined, but the individual probability of layoff $\tau(i)$ is not.*

Proof For each optimal policy, eq. (5) determines the firm's total layoffs

$$\int_0^n \tau(i) di = n - \frac{n' - n_h}{1 - \lambda p(\theta(S, x^*(S)))}. \quad (18)$$

As long as total layoffs are constant, any perturbation of individual layoff probabilities $\{\tau(i)\}_{i \in [0, n]}$ does not affect the firm's value. \square

The key reason Lemma 2.1 holds is homogeneous workers, so the distribution of layoff probabilities is irrelevant. Therefore, I will focus on the symmetric decision rule that all employees face the same layoff probability throughout the rest of this paper.

2.5 Firm's Default Decision and Cash on Hand

To further reduce the number of dimensions, I next explore the firm's default decision and rewrite the firm's problem using cash on hand as a state variable.

Notice that the outside value is zero when a firm exits, so a firm defaults and exits when it cannot satisfy the non-negative equity payout constraint (4). Define cash on hand X as:

$$X = Azn^\alpha - n[\bar{u} + (1 - \lambda)\mu(S)] - \bar{w}_m - \epsilon - b, \quad (19)$$

where $\mu(S) \equiv \max_x p(\theta(S, x))[x - \beta \mathbb{E} U(S')]$. Then, a firm defaults if and only if:

$$X + M(S, z, n) < 0, \quad (20)$$

where $M(S, z, n)$ is maximum net borrowing as defined in equation (12). Therefore, a firm's default decision can be summarized by the operating cost cutoff $\bar{\epsilon}(S, z, b, n)$, defined as:

$$\bar{w}_m + \bar{\epsilon}(S, z, b, n) \equiv Azn^\alpha - \int_0^n w(i)di - b + M(S, z, n). \quad (21)$$

So, the firm defaults when the operating cost is higher than the cutoff $\bar{\epsilon}(S, z, b, n)$ such that the firm cannot satisfy the non-negative equity payout constraint, i.e.,

$$d(S, s, b, n) = \begin{cases} 0, & \text{if } \epsilon \leq \bar{\epsilon}(S, z, b, n), \\ 1, & \text{if } \epsilon > \bar{\epsilon}(S, z, b, n). \end{cases} \quad (22)$$

Plugging in the default cutoff (21) and wages (16) and (17), I rewrite the firm's problem (3) using cash on hand X as a state variable:

$$V(S, z, X, n) = \max_{\substack{\Delta, b', n', \\ \tau, n_h, x_h}} \Delta + \beta(1 - \pi_d) \mathbb{E}_{S', z' | S, z} \int_{-\infty}^{\bar{\epsilon}(S', z', b', n')} V(S', z', X', n') d\Phi(\epsilon') \quad (23)$$

$$\text{s.t. (6),} \quad (24)$$

$$n' = (1 - \tau)(1 - \lambda p(\theta(S, x^*(S))))n + n_h, \quad (25)$$

$$\Delta = X + Q(S, z, b', n')b' - n_h \frac{c}{q(\theta(S, x_h))} - n_h[x_h - \beta \mathbb{E} U(S')] \geq 0, \quad (26)$$

$$X' = A'z'n^\alpha - n'[\bar{u} + (1 - \lambda)\mu(S')] - \bar{w}_m - \epsilon' - b', \quad (27)$$

$$\bar{w}_m + \bar{\epsilon}(S', z', b', n') = A'z'n^\alpha - n'[\bar{u} + (1 - \lambda)\mu(S')] - b' + M(S', z', n'), \quad (28)$$

$$Q(S, z, b', n')b' - n_h \frac{c}{q(\theta(S, x_h))} - n_h[x_h - \beta \mathbb{E}U(S')] \geq M(S, z, n) - F_m(S, z). \quad (29)$$

The non-negative equity payout constraint (26) reveals that firms' decisions depend on cash on hand X . When cash on hand is too low, the firm defaults because it cannot fully pay wages and debts. On the other hand, when cash on hand is sufficiently high, the firm is not constrained by (26). In this case, the firm solves the following relaxed problem:

$$\hat{V}(S, z, X, n) = \max_{\substack{b', n', \\ \tau, n_h, x_h}} X + Q(S, z, b', n')b' - n_h \frac{c}{q(\theta(S, x_h))} - n_h[x_h - \beta \mathbb{E}U(S')] \quad (30)$$

$$+ \beta(1 - \pi_d) \mathbb{E}_{S', z' | S, z} \int_{-\infty}^{\bar{\epsilon}(S', z', b', n')} V(S', z', X', n') d\Phi(\epsilon')$$

$$\text{s.t. (6), (25), (27), (28), and (29).} \quad (31)$$

For the relaxed problem, cash on hand does not affect the firm's choices. Let $\hat{b}(S, z, n)$, $\hat{n}(S, z, n)$, $\hat{\tau}(S, z, n)$, $\hat{n}_h(S, z, n)$, and $\hat{x}_h(S, z, n)$ denote the optimal policies for the relaxed problem. The following Lemma 2.2 characterizes firms' decisions with respect to cash on hand.

Lemma 2.2 (*Decision Cutoffs*): *If $X < -M(S, z, n)$, the firm cannot satisfy the nonnegative external equity payout condition and has to default. If $X \geq \hat{x}(S, z, n) \equiv -\{Q(S, z, \hat{b}, \hat{n})\hat{b} - \hat{n}_h \frac{c}{q(\theta(S, \hat{x}_h))} - \hat{n}_h[\hat{x}_h - \beta \mathbb{E}U(S')]\}$, the firm solves the relaxed problem (30), and the level of cash on hand does not affect the optimal decisions.*

Proof If the firm's cash on hand X is less than $-M(S, z, n)$, even though the firm borrows as much as possible, it cannot make nonnegative external equity payouts. So, the firm defaults and exits. If the firm's cash on hand X is more than $\hat{x}(v, z, n)$, then $(\hat{b}, \hat{n}, \hat{\tau}, \hat{n}_h, \hat{x}_h)$ is also the solution to the firm's problem (23), because constraint (26) holds automatically. In this case, cash on hand does not affect any constraints, and the optimal decisions do not depend on cash on hand. \square

Lemma 2.2 provides the method to solve the firm's problem by level of cash on hand. This partitioning method has been used by Khan and Thomas (2013), Arellano, Bai and Kehoe (2019), and Ottonello and Winberry (2020).

2.6 Bond Pricing

I assume that the economy's financial market is small compared with the rest of the world, so the risk-free interest rate in the international financial market is exogenous. This assumption ensures the block recursivity and thus computational tractability.

International financial intermediaries supply one-period bonds to firms. They are risk-neutral and competitive. The opportunity cost of lending is the risk-free interest rate r in the world financial market, equal to $1/\beta - 1$. Financial intermediaries break even when lending to firms. If the firm defaults, financial intermediaries can recover a value proportional to the firm's expected income $A'z'n'^\alpha - w(S)n' - \bar{m} - \mu_\epsilon$. This recovery function indicates that lenders can recover more when the firm has a higher value. [Lian and Ma \(2021\)](#) shows that this earnings-based lending prevails in the U.S.

Let η denote the recovery rate. And the break-even bond price $Q(S, z, b', n')$ is:

$$Q(S, z, b', n') = \beta \mathbb{E}_{S', z' | S, z} \left\{ (1 - \pi_d) \Phi(\bar{\epsilon}(S', z', b', n')) + [1 - (1 - \pi_d) \Phi(\bar{\epsilon}(S', z', b', n'))] \min \left\{ \eta \frac{A'z'n'^\alpha - w(S)n' - \bar{w}_m - \mu_\epsilon}{b'}, 1 \right\} \right\}. \quad (32)$$

2.7 Firm Entry

Potential new firms pay a fixed cost k_e to enter. New entrants' productivity will be drawn from the stationary distribution of idiosyncratic productivity $g_z(\cdot)$. New entrants do not produce in the entry period but hire workers as do incumbent firms. New firms start with zero debt and no labor. Then the new entrant's problem is:

$$J_e(S, z) = \max_{n_h, x_h} -n_h \frac{c}{q(\theta(S, x_h))} - n_h [x_h - \beta \mathbb{E} U(S')] \quad (33)$$

$$+ \beta(1 - \pi_d) \mathbb{E}_{S', z' | S, z} \int_{-\infty}^{\bar{\epsilon}(S', z', b_0, n_h)} V(S', z', X', n_h) d\Phi(\epsilon'), \quad (34)$$

$$\text{s.t. } b_0 = 0, \text{ (27), and (28).} \quad (35)$$

I use n_e , x_e , and d_e to denote the new entrant's optimal policies.

Notice that both incumbent firms and new entrants only post vacancies in the markets with the lowest hiring cost. Define the minimum hiring cost per worker as

$$\kappa(S) \equiv \min_{x_h} [x_h + \frac{c}{q(\theta(S, x_h))}]. \quad (36)$$

In equilibrium, only submarkets with the lowest hiring cost are active. Given the equilibrium hiring cost $\kappa(S)$, the mapping from the market's promised utility x to the market intensity θ is

$$\theta(S, x) = \begin{cases} q^{-1} \left(\frac{c}{\kappa(S) - x} \right), & \text{if } x \leq \kappa(S) - c, \\ 0, & \text{if } x \geq \kappa(S) - c. \end{cases} \quad (37)$$

Notice that the upper bound of the vacancy filling probability q is one. When the submarket's

promised utility x is higher than $\kappa - c$, no firm posts vacancies there because the vacancy filling probability cannot be greater than one to compensate for the hiring cost. In this case, the market is inactive, and the market intensity is zero.

The value of $\kappa(S)$ is determined by the free entry condition, which requires that the entry cost equals the expected entry value:

$$k_e = \sum_z J_e(S, z) g_z(z), \forall S. \quad (38)$$

Therefore, the free entry condition closes the model by pinning down the hiring cost $\kappa(S)$ for all aggregate states S .

2.8 Equilibrium

This section defines the block recursive equilibrium of the model.

Definition 2.1 Let s^f summarize the firm's state variables (S, z, X, n) . The block recursive equilibrium consists of the policy and value functions of unemployed workers $\{x_u(S), U(S)\}$; of employed workers $\{x(S, s, C), W(S, s, C)\}$; of incumbent firms $\{\Delta(s^f), b'(s^f), n'(s^f), \tau(s^f), n_h(s^f), x_h(s^f), w(S), w_h(S)\}$; of new firms $\{n_e(S), x_e(S), J_e(S)\}$; the hiring cost per worker $\kappa(S)$; the labor market tightness function $\theta(S, x; \kappa(S))$; and bond price schedules $Q(S, z, b', n')$ such that

1. Given the bond price schedules, the hiring cost, and the labor market tightness, the policy and value functions of unemployed workers, employed workers, incumbent firms, and entering firms solve their respective problems (1), (2), (16), (17), (23), and (33).
2. The bond price schedule satisfies (32).
3. The hiring cost per worker and the labor market tightness function satisfy (36) and (37).
4. The free entry condition (38) holds.

2.9 Aggregate Transitions

Let $\Upsilon(z, X, n)$ denote the mass of firms with states (z, X, n) , which is the sum of incumbent firms and new entrants which do not default. The law of motion of the firm distribution is:

$$\begin{aligned} \Upsilon'(z', X', n') &= \sum_{z, X, n, \epsilon'} (1 - \pi_d)(1 - d(S', s'; S, z, X, n)) \mathbb{1}\{X'(S', s'; S, z, X, n) = X'\} \phi(\epsilon') \pi_z(z'|z, \sigma) \mathbb{1}\{n'(S, z, X, n) = n'\} \Upsilon(z, X, n) \\ &\quad + m_e(S, \Upsilon) \sum_{z, \epsilon'} (1 - \pi_d)(1 - d_e(S', s'; S, z)) \mathbb{1}\{X'_e(S', s'; S, z) = X'\} \phi(\epsilon') \pi_z(z'|z, \sigma) \mathbb{1}\{n_e(S) = n'\} g_z(z). \end{aligned} \quad (39)$$

Following [Arellano, Bai and Kehoe \(2019\)](#), I assume that defaulting firms can still produce as long as their sales can cover the minimum wage required to retain workers for production. As discussed in Section 2.3, the necessary wage equals the unemployment benefits. These firms' employees will be laid off after production occurs and search for new jobs in the labor market, so they are not counted in unemployment in the current period. This setup relieves the concern that varying default rates mechanically drive the fluctuations of output and unemployment. Let $d^p(S', s'; S, z, X, n)$ be the production indicator, which equals one if and only if the firm does not default or satisfies $A'z'n'^\alpha > \bar{u}n'$ and zero otherwise. I use $\Upsilon^p(z, n)$ to denote the distribution of producing firms, which thus evolves per:

$$\begin{aligned} \Upsilon^p(z', n') &= \sum_{z, X, n, \epsilon'} (1 - \pi_d)(1 - d^p(S', s'; S, z, X, n)) \pi_z(z'|z, \sigma) \mathbb{1}\{n'(S, z, X, n) = n'\} \Upsilon(z, X, n) \\ &\quad + m_e(S, \Upsilon) \sum_{z, \epsilon'} (1 - \pi_d)(1 - d_e^p(S', s'; S, z)) \pi_z(z'|z, \sigma) \mathbb{1}\{n_e(S) = n'\} g_z(z). \end{aligned} \quad (40)$$

The mass of entrants $m_e(S, \Upsilon)$ is determined such that total jobs found by workers equals the total jobs created by incumbent firms and new entrants:¹³

$$JF_{\text{workers}}(S, \Upsilon) = JC_{\text{incumbents}}(S, \Upsilon) + m_e(S, \Upsilon) JC_{\text{entrants}}(S, \Upsilon), \quad (41)$$

¹³ Over the business cycle, jobs created by incumbent firms, $JC_{\text{incumbents}}$, can occasionally be larger than jobs found by workers, JF_{workers} . If the total mass of workers is restricted to one, then entry will be negative and not well-defined. To deal with this issue, I assume that when incumbent firms hire more workers than find jobs, the entry m_e is zero, and the mass of workers increases such that equation (41) holds. Then I normalize the economy so that the mass of workers is one unit again. This setup can be understood as an increase in labor force participation. Simulation shows that the average annual population growth rate is less than 0.5%, implying that the potential problem of negative entry is small. Another way to solve this problem is to assign different entry costs for different aggregate states. See [Kaas and Kircher \(2015\)](#) for this treatment.

where

$$JF_{\text{workers}}(S, \Upsilon) = p(\theta(S, x_u^*(S))) \left(1 - \sum_{z, X, n} n \Upsilon(z, X, n) \right) + \sum_{z, X, n} \lambda p(\theta(S, x^*(S))) n \Upsilon(z, X, n), \quad (42)$$

$$JC_{\text{incumbents}}(S, \Upsilon) = \sum_{z, X, n} n_h(S, z, X, n) \Upsilon(z, X, n), \quad (43)$$

$$JC_{\text{entrants}}(S, \Upsilon) = \sum_z g_z(z) n_e(S, z). \quad (44)$$

The unemployment rate u evolves as:

$$\begin{aligned} u' = & (1 - p(\theta(S, x_u^*(S))))u + \sum_{z, X, n} n \tau(S, z, X, n) \Upsilon(z, X, n) \\ & + \sum_{\substack{z', \epsilon', \\ z, X, n}} [\pi_d + (1 - \pi_d) d(S', s'; S, z, X, n)] \pi_\epsilon(\epsilon') \pi_z(z' | z, \sigma) n'(S, z, X, n) \Upsilon(z, X, n) \\ & + m_e(S, \Upsilon) \sum_{z', \epsilon', z} [\pi_d + (1 - \pi_d) d_e(S', s'; S, z)] \pi_\epsilon(\epsilon') \pi_z(z' | z, \sigma) n_e(S, z) g_z(z). \end{aligned} \quad (45)$$

and aggregate output is the sum of all firms' output

$$Y = \sum_{z, n} A z n^\alpha \Upsilon^p(z, n). \quad (46)$$

2.10 Discussions of the Assumptions

My model's key assumption and driving force is the incompleteness of financial instruments and labor contracts. This section discusses and justifies this assumption.

First, I assume that firms can only borrow through state-uncontingent debt. Beyond the inherent plausibility given the widespread real-world existence of state-uncontingent debt, much related literature uses this assumption to model firms' default risks (Arellano, Bai and Kehoe, 2019; Khan and Thomas, 2013; Ottonello and Winberry, 2020). I also assume that firms can only have non-negative equity payouts. This assumption ensures that firms do not have deep pockets by issuing large amounts of equity, which in turn guarantees that financial frictions are meaningful in my model. Empirically, according to the calculations in Schoefer (2021) using U.S. Flow of Funds data, the average equity raised by U.S. firms from 1951Q4 to 2019Q4 is negative because of share repurchases. Therefore, on average equity issuance is not a primary financing tool for U.S. firms. Admittedly, a more realistic model could have equity issuance, but the recalibration will indicate sizable equity issuance costs. I conjecture that my model's implications would thus not change much. Therefore, I follow the literature to exclude equity financing for simplicity.

Second, novel to the search literature, I assume that labor contracts do not insure firms from idiosyncratic shocks. Specifically, the promised utility is assumed to have a state-uncontingent utility markup over the unemployment value. The state-uncontingency makes wages debt-like commitments that firms are less likely to take on when volatility is high. This mechanism helps my model explain unemployment better than [Schaal \(2017\)](#).

The assumption of state-uncontingency distinguishes my framework from the textbook Diamond–Mortensen–Pissarides search models and a subsequent group of models assuming wage rigidity. As [Shimer \(2005\)](#) points out, typical search models cannot generate the observed unemployment volatility because wage movements largely cancel out the employment impacts of aggregate productivity shocks in equilibrium. One of the solutions to Shimer’s puzzle is wage rigidity ([Hall, 2005](#)). However, whether wage rigidity is a proper assumption to explain unemployment is still an open question ([Kudlyak, 2014](#); [Pissarides, 2009](#); [Rudanko, 2009](#)). To clarify, instead of making the debatable assumption of wage rigidity, I allow wages to vary with the outside value of unemployment. That is, wages can still decrease to offset the effects of aggregate shocks as in textbook search model. The difference is that I assume labor contracts do not allow firms to hedge idiosyncratic risks. My quantitative results show that the micro-level risk caused by wage commitments is the key to explaining unemployment dynamics over business cycles. On the other hand, suppose the labor contract is state-contingent. Then it will be a much better financial instrument than state-uncontingent debt. I conceive this implication as counterfactual.

To justify the state-uncontingency of labor contracts, Appendix [D](#) provides a micro-founded theory of information frictions. The idea is based on [Hall and Lazear \(1984\)](#). When workers do not clearly observe firm shocks, firms have the incentive to lie to workers to pay lower wages. Workers know this, so they do not accept wage cuts when the firm declares a bad shock. Therefore, the incentive-compatible lifetime promised utility features a state-uncontingent utility markup over the worker’s outside value.

The state-uncontingency of labor contracts can be tested empirically. One implication or potential criticism is that it will cause inefficient separations. However, [Jäger, Schoefer and Zweimüller \(2019\)](#) show that separations are indeed inefficient in the data. Using a quasi-experimental repeal of an unemployment insurance extension in Austria, they do not find that surviving jobs display higher resilience. This implies that separated jobs are not simply the ones with the lowest surplus. In line with their conclusion of inefficient separations, my assumption of state-uncontingent labor contracts can also have similar implications.

With both types of incompleteness, my financial channel of wage commitments can improve a search model’s performance in explaining unemployment. Moreover, there has been empirical evidence in the existing literature to support the interaction between finance and labor. [Favilukis, Lin and Zhao \(2020\)](#) find that wage growth and labor shares are the primary factors predicting credit spreads. [Donangelo et al. \(2019\)](#) use Census data and find that firms with higher labor

shares are more sensitive to shocks. [Schoefer \(2021\)](#) shows that industries with higher labor shares are associated with more procyclical cash flows.

3 Quantitative Analysis

In this section, I first parametrize the model by matching moments. Then I explain the mechanism and show the critical connection between financial frictions and volatility shocks and unemployment volatility. Next, I apply the model to U.S. business cycles to see to what degree the model can explain unemployment dynamics during recessions. Finally, I conduct policy experiments to investigate the labor market policies of the U.S. and Germany during the recent Covid recession.

I use grid search to solve the problem numerically. The global solution is computationally tractable because of block recursivity.

3.1 Parameterization

There are four shocks (A, σ, z, ϵ) in the economy. The logs of aggregate productivity and volatility both follow AR(1) processes:

$$\log A_{t+1} = \rho_A \log A_t + \sigma_A \sqrt{1 - \rho_A^2} \epsilon_t^A, \quad (47)$$

$$\log \sigma_{t+1} = (1 - \rho_\sigma) \log \bar{\sigma} + \rho_\sigma \log \sigma_t + \sigma_\sigma \sqrt{1 - \rho_\sigma^2} \epsilon_t^\sigma, \quad (48)$$

where the innovations ϵ_t^A and ϵ_t^σ follow the standard normal distribution. I follow [Schaal \(2017\)](#) and allow ϵ_t^A and ϵ_t^σ to be correlated with the correlation coefficient $\rho_{A\sigma}$.

Firm j 's idiosyncratic productivity also follows an AR(1) process:

$$\log z_{jt+1} = \rho_z \log z_{jt} + \sigma_z \sqrt{1 - \rho_z^2} \epsilon_{jt}^z, \quad (49)$$

where ϵ_{jt}^z follows the standard normal distribution, and the volatility shock σ_t controls the standard deviations of the innovation.

The i.i.d. operating cost shock ϵ 's distribution, $\Phi(\cdot)$, is normally distributed with mean μ_ϵ and standard deviation σ_ϵ .

I follow [Menzio and Shi \(2010\)](#) and [Schaal \(2017\)](#) in using the following job finding probability function:

$$p(\theta) = \theta(1 + \theta^\gamma)^{-1/\gamma}. \quad (50)$$

Accordingly, the vacancy-filling rate $q(\theta)$ is $p(\theta)/\theta$.

I calibrate the parameters as closely as possible to [Schaal \(2017\)](#) for comparison. Table 1 shows the parameter values. The parameters in Panel A are exogenously assigned, following the literature. The quarterly discount factor β equals 0.988, corresponding to a 5% annual risk-free interest rate. The labor coefficient α is set as 0.66 to be consistent with the wage share. I follow [Khan and Thomas \(2008\)](#) to set the persistence of idiosyncratic productivity ρ_z as 0.95.

The remaining parameters in Panel B are calibrated by matching moments using U.S. data. Table 2 shows the moments in the data and the model. Because of the model's non-linearity, all parameters influence all moments jointly. However, each moment is primarily affected by certain parameters, and I organize them into four groups accordingly. The first two groups of parameters are related to aggregate shocks and the labor market, which are calibrated according to [Schaal \(2017\)](#). The other two groups of parameters, associated with the financial market and firm exit, are added upon [Schaal's \(2017\)](#) calibration for my financial channel.

The first set of parameters controls the AR(1) processes of aggregate shocks. For the aggregate productivity parameters (ρ_A, σ_A) , I use the autocorrelation and standard deviation of output as target moments. The data moments are calculated by [Schaal \(2017\)](#) using real GDP from the Bureau of Economic Analysis. He detrends the time series of output by an HP-filter with a parameter of 1,600 to obtain the log deviations.

To calibrate the process of volatility shocks, I follow [Bloom et al. \(2018\)](#) to use the interquartile range of sales growth rates across firms (IQR) to reflect the degree of volatility in the economy. I obtain the sales of firms from CRSP-Compustat, which provides balance sheet data of publicly listed firms. I use the Consumer Price Index for All Urban Consumers (CPI) to deflate sales. To avoid the composition of firms influencing the IQR, I follow [Bloom et al. \(2018\)](#) and use only firms with at least 100 quarters of observations. I also drop firms in the finance and public administration sector. I also follow [Davis and Haltiwanger \(1992\)](#) by measuring the sales growth rate at quarter t as $(y_t - y_{t-4})/((y_t + y_{t-4})/2)$, so growth rates are less affected by extreme values of sales. Next, because firms may respond heterogeneously to shocks in different industries, the IQR of the original sales growth rates may reflect not only the underlying volatility shocks but also heterogeneous responses. Therefore, I follow [Bloom et al. \(2018\)](#) and [Schaal \(2017\)](#) and measure volatility controlling for firms' permanent heterogeneity and industry heterogeneity over business cycles. Specifically, I project firms' sales growth on firm-level fixed effects and industry-quarter fixed effects to obtain residuals of sales growth¹⁴ and use these residuals as my measure of volatility to construct the IQR. Given the time series of IQR, I compute its mean, detrend the time series with an HP-filter, and compute the autocorrelation and standard deviations to serve as targets for the volatility shock parameters $(\mu_\sigma, \rho_\sigma, \sigma_\sigma)$. I also use the correlation between output and IQR to pin down the correlation between aggregate productivity shocks and volatility shocks $\rho_{A\sigma}$. The output data is quarterly real GDP per capita from the Bureau of Economic Analysis,

¹⁴ Firm industry is based on the Standard Industrial Classification (SIC) at the 3-digit level.

Table 1: Parameter Values

Parameters	Notation	Value	Source/Matched Moment
Panel A: Assigned Parameters			
Discount factor	β	0.988	5% annual interest rate
Decreasing returns to scale coefficient	α	0.66	Labor share
Persistence of productivity	ρ_z	0.95	Khan and Thomas (2008)

retrieved from FRED. It is detrended by the HP-filter with 1,600 as the parameters to obtain the log deviations.

The second group of parameters is related to the labor market. The unemployment utility \bar{u} is the opportunity cost of working, affecting wages and thus firms' firing decision; the vacancy posting cost c primarily affects firms' hiring decisions; and the relative on-the-job search efficiency λ influences the probability of job-to-job transitions. I calibrate these three parameters using the transition probability from employment to unemployment (EU), the transition probability from unemployment to employment (UE), and the transition probability from employment to employment (EE). The data moments for EU, UE, and EE are the quarterly versions of the monthly ones in [Schaal \(2017\)](#), who obtains the monthly EU and UE rates from [Shimer \(2005\)](#) and the EE rate from [Nagypál \(2007\)](#). The matching function elasticity γ is calibrated to match the elasticity of UE rates to the labor market intensity θ , which [Schaal \(2017\)](#) obtains from [Shimer \(2005\)](#). The

Table 2: Matched Moments

Exit					
Annual exit rate (%)	8.9	9.0	9.2	9.0	9.1

Notes: This table shows the targeted data moments and moments matched by the benchmark model and the model without financial frictions. $A + \sigma$ means the model has both aggregate productivity shocks and volatility shocks, and A means the model only has aggregate productivity shocks. Table 5 reports the recalibrated parameters of the four models.

entry cost k_e is calibrated to match the share of jobs created by entrants, which is calculated by Schaal (2017) using Business Employment Dynamics (BED). The mean operating cost affects firms' exit decisions and thus can be pinned down by the average establishment size, measured by Schaal (2017) using the 2002 Economic Census. Notice that the mean operating cost μ_ϵ and the manager's wage \bar{w}_m symmetrically influence firms' cash on hand, so I calibrate $\mu_\epsilon + \bar{w}_m$ using the average establishment size.

Parameters in the third group deal with the financial market. First, I use the average credit spread to calibrate the standard deviation of the operating cost, σ_ϵ . The credit spread is the difference between the yield on Baa and Aaa corporate bonds. The data source is Moody's, retrieved from FRED, Federal Reserve Bank of St. Louis. Correspondingly, the credit spread in the model is the annualized difference between the actual borrowing cost and the risk-free interest rate:

$$\frac{1}{Q(v, z, b', n')} - \frac{1}{\beta}. \quad (51)$$

Because the agency friction constraint incentivizes firms to borrow, I use the median leverage of firms to calibrate the agency friction parameter $\tilde{\zeta} \equiv \zeta / (\bar{w}_m + (1 - \lambda) \frac{\beta}{1-\beta} \bar{w}_m)$. Leverage is the ratio of the firm's total debt to its annualized sales. The data moment of median leverage is from [Arellano, Bai and Kehoe \(2019\)](#). Next, I use the correlation between output and credit spreads to parameterize the auditing technology ξ , and I use the correlation between IQR and credit spreads for the recovery rate η . Targeting the two correlations anchors the effects of aggregate productivity shocks and volatility shocks through the financial channel.

The last parameter is the exogenous exit rate π_d , which helps generate exits beyond defaults. I use the annual exit rate calculated from Business Dynamics Statistics (BDS) to calibrate π_d .

3.2 Differences from the Calibration of [Schaal \(2017\)](#)

My parametrization is based on [Schaal \(2017\)](#) when estimating parameters related to aggregate shocks and the labor market. I follow his calibration closely except for the following three differences.

First, [Schaal \(2017\)](#) uses a monthly frequency, while my model's frequency is quarterly. I choose the quarterly frequency to accommodate the data moments related to the financial market. As is common in the finance literature, leverage should be one of the target moments, defined as a firm's debt over annualized sales. In a quarterly model, annualized sales in the denominator equal four times the quarterly sales. However, suppose the model is monthly. Annualized sales in the denominator will be 12 times the monthly sales. Therefore, when targeting the same median leverage in the data, the monthly model implies the firm's debt is much higher than its per-period sales, and the default risks will be counterfactually high. Thus, I follow the finance literature and use a quarterly model.

Second, [Schaal \(2017\)](#) uses 0.85 as the decreasing returns to scale coefficient α , and I use 0.66. Neither of us explicitly models capital, while [Schaal \(2017\)](#) chooses 0.85 to approximate the total decreasing returns. But he also points out that the results are unaffected when targeting a labor share of 0.66. Because my mechanism is about wage commitments, I choose to target the wage share so that the size of firm commitments is consistent with the data. If I used 0.85 as the decreasing returns to scale coefficient, wage commitments would be larger, increasing the risk to firms and generating counterfactually high credit spreads.

Third, to calibrate the volatility shock process, [Schaal \(2017\)](#) uses the interquartile range (IQR) of innovations to idiosyncratic productivity calculated by [Bloom et al. \(2018\)](#). Instead, I follow both [Bloom et al. \(2018\)](#) and [Arellano, Bai and Kehoe \(2019\)](#) and use the IQR of firms' sales growth rates. I make this deviation because targeting the IQR of innovations to idiosyncratic productivity leads to a counterfactually high sales volatility. Specifically, the IQR of sales growth in the model will

be more than five times the data. Because sales volatility determines firm default probability, the counterfactually high volatility of sales leads to counterfactually large default rates and extremely high credit spreads. To keep the magnitude of financial effects reasonable, I use the IQR of firms' sales growth rates as in [Arellano, Bai and Kehoe \(2019\)](#), who also model volatility shocks and financial frictions simultaneously. The main difference between using the IQR of firms' sales growth rates and the IQR of idiosyncratic productivity innovations is the level of volatility $\bar{\sigma}$.¹⁵ But, they have very similar business cycle behaviors in terms of innovations to volatility, i.e., ϵ_t^σ . In particular, Figure 8 compares the log deviations of imputed aggregate productivity shocks and volatility shocks with [Schaal \(2017\)](#), showing that the two volatility shocks have similar variations over business cycles.

As a validation of this calibration choice, Table 3 shows that my counterfactual model without financial frictions has very similar business cycle statistics to [Schaal \(2017\)](#). Further, Figure 5 displays the changes in unemployment during recessions, and the model without financial frictions also yields very similar patterns to [Schaal \(2017\)](#). Therefore, our divergence in calibration is not the main reason for our different quantitative performances.

3.3 Business Cycle Statistics

To assess how well my model can explain business cycles, I report simulated business cycle statistics in Table 3. To compute the moments, I simulate the model for 3,000 quarters and use the log deviations from an HP-filter trend with a smoothing parameter of 1,600. Beyond the benchmark model, I consider three alternative models for comparison. All models are recalibrated by matching the same moments. Table 2 contains the calibration results and Table 5 reports the recalibrated parameters.

Since all models are calibrated, they have similar predictions for output and labor productivity in the first two columns, and I will focus on their differences in terms of unemployment volatility in brief. The next section will investigate the mechanism in greater detail.

Benchmark Model With Both Shocks. The standard deviation of unemployment is 0.121 in the data (Panel A), and my benchmark model with both aggregate productivity shocks and volatility shocks can generate a standard deviation of 0.106 (Panel B), which is 10 percent higher than the 0.090 in [Schaal \(2017\)](#). Next, I use three alternative models to explain the roles of both financial frictions and volatility shocks in my model's quantitative performance.

Benchmark Model With Only Aggregate Productivity Shocks. The second part of Panel B calibrates the same model but keeps only the aggregate productivity shocks, i.e., the volatility of firms' idiosyncratic productivity is no longer time-varying. Now the model only generates

¹⁵ One concern about the idiosyncratic productivity measured by [Bloom et al. \(2018\)](#) is that they use revenue TFP, which can reflect firm pricing power instead of productivity ([Bils, Klenow and Ruane, 2021](#); [Hsieh and Klenow, 2009](#)).

Table 3: Business Cycle Statistics

	Y	Y/L	U	V	Hirings	Quits	Layoffs	Wages

<i>Only A Shock</i>								
Std Dev.	0.017	0.014	0.069	0.064	0.023	0.023	0.047	0.012
cor(Y,x)	1	0.994	-0.876	0.906	-0.024	0.975	-0.787	0.985

Notes: Panel A shows the business cycle moments in the data. Panels B and C report moments of 3,000-quarter simulations of the benchmark model and the model without financial frictions, with and without volatility shocks. Both the data and the model simulations are log-detrended by the HP filter with smoothing parameter 1600. Consistent with [Schaal \(2017\)](#), Y denotes output, Y/L is output per worker, U represents unemployment, and V is vacancies.

a standard deviation of unemployment of 0.079. This finding implies that volatility shocks are necessary for the financial channel's effectiveness. Distinguished from aggregate productivity shocks, the offsetting effect of equilibrium wages is much smaller for volatility shocks. High volatility spreads the distribution of firms' idiosyncratic productivity, and high productivity firms may still benefit from elevated volatility, which props up wages. This is called as the Oi-Hartman-Abel effect ([Oi \(1961\)](#), [Hartman \(1972\)](#), [Abel \(1983\)](#)) in the volatility literature. Therefore, though wages still decline when volatility is high, the decline is much smaller than when it is a negative aggregate productivity shock.

Model Without Financial Frictions and With Both Shocks. The first part of Panel C shows the results when the model does not have financial frictions but has both shocks. It generates a 0.088 standard deviation of unemployment, in line with the 0.090 in [Schaal \(2017\)](#). Comparing it with the 0.106 of the benchmark model reveals the important role of financial frictions in the model. Without financial frictions, my model is similar to [Schaal \(2017\)](#). Adding the financial channel amplifies the effect of aggregate shocks on unemployment and generates more unemployment volatility.

Model Without Financial Frictions and With Only Aggregate Productivity Shocks. I show the model statistics without financial frictions and with only the aggregate productivity shock in the second part of Panel C. It generates a standard deviation of unemployment of 0.069, consistent with the 0.067 in the corresponding model of [Schaal \(2017\)](#). This number is similar to the benchmark model with only the aggregate productivity shock, and confirms the complementarity between volatility shocks and the financial channel of wage commitments.

3.4 Inspecting the Mechanism

In this section, I explain the mechanism in my model. First, I show how the interaction between the financial channel of wage commitments and volatility shocks works. Next, I illustrate the importance of the financial channel by comparing it with the recalibrated model without financial frictions. Finally, I explain why the mechanism needs to interact with volatility shocks.

3.4.1 The Financial Channel of Wage Commitments

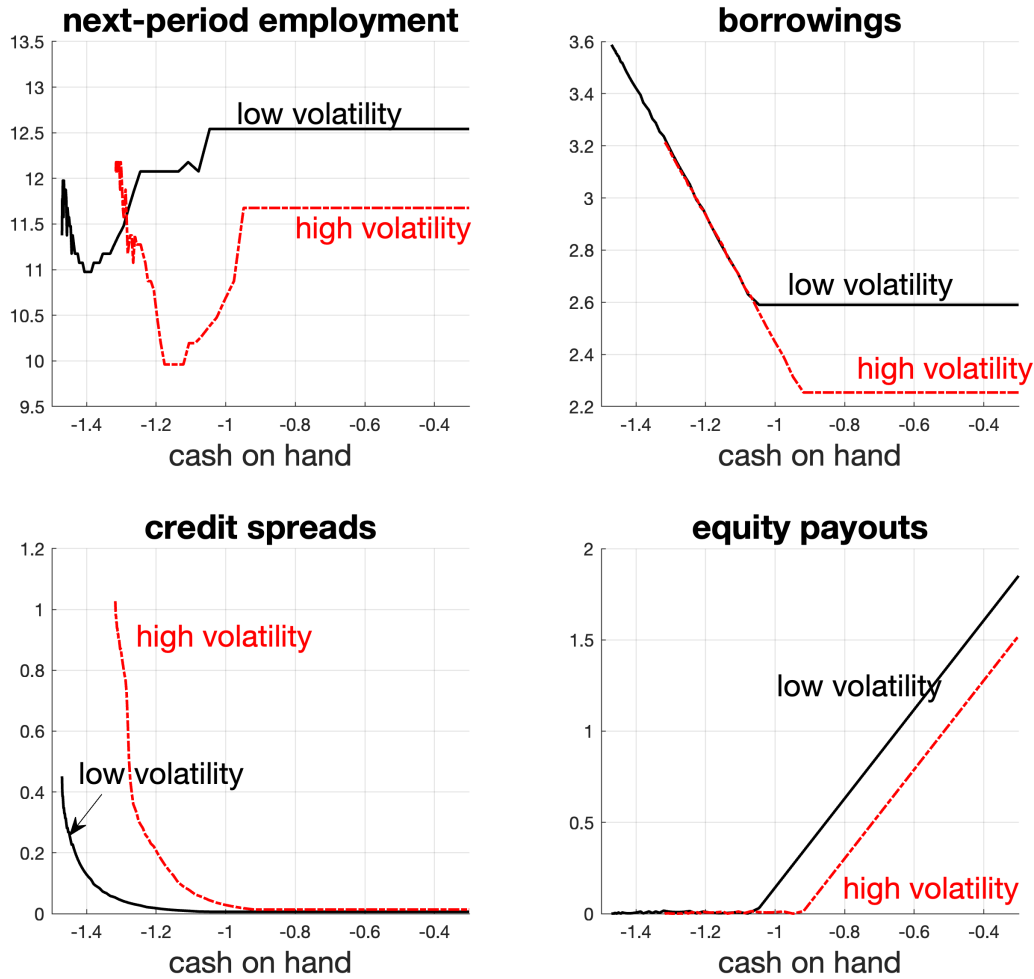

I use the firm's decision rules to explain how high volatility leads firms to cut employment due to financial concerns over wage payments.

Figure 2 shows how firms' decisions depend on cash on hand X and the level of volatility. I vary the cash on hand on the horizontal axis and fix the firm's idiosyncratic productivity and employment at their median levels. The decision rules are next-period employment n' , borrowing Qb' , credit spread $1/Q - 1/\beta$, and equity payouts Δ . The solid black lines are for the low volatility state, one unconditional standard deviation below the mean volatility. The dash-dot red lines are for the high volatility state, one unconditional standard deviation higher than the mean. The decision rules are in line with the patterns in [Arellano, Bai and Kehoe \(2019\)](#) because both models have similar financial channels.

First, the relations between the decision rules and cash on hand are consistent with Lemma 2.2. When cash on hand is higher than a cutoff, firms' employment, borrowing, and credit spreads no longer depend on cash on hand. The equity payouts increase with cash on hand one for one in this case. When below the cutoff, the equity payout is zero because the non-negative equity payout constraint binds.¹⁶ As cash on hand decreases, firms need to borrow more to satisfy the non-negative equity payout constraint. Credit spreads subsequently rise. Employment for the next period decreases as cash on hand decreases because firms face higher default risks and cut employment to avoid defaulting on wage payments next period. But when cash on hand is very low, firms hire slightly more workers. The reason is the increased default probability. Conditional on survival, firms have higher expected productivity. Thus, firms decide to take on more risk and

¹⁶ The slight difference between zero is due to computational errors of grid search.

Figure 2: Decision Rules with Different Volatilities

Notes: The four panels plot a median firm's decision rules for next-period employment, borrowing, credit spread, and equity payouts with respect to cash on hand. The solid black lines are for the low volatility state, and the dash-dot red lines are for the high volatility state. Aggregate productivity is set at the high level. "High" or "low" means one unconditional standard deviation above or below the mean. The firm's idiosyncratic productivity and current employment are fixed at their median levels.

hire more workers.

Second, firms' decisions depend on the level of volatility. Higher volatility implies greater default risks because of the larger probability of drawing low productivity, resulting in higher credit spreads. Therefore, firms are tentative about borrowing and equity payouts. For a similar reason, firms also decrease the number of employees in high volatility states. Intuitively, firms make employment decisions, i.e., search, matching, and separation, in the labor market before knowing tomorrow's productivity. The committed wage payments are like debts in this sense, which firms have to pay or default in the next period. If the firm draws low productivity next period, wages can be too high compared to sales, and firms may default and be liquidated. Because

of these concerns over meeting payroll, firms are precautionary in making commitments during high volatility periods. Low demand leads to higher unemployment. This is the key mechanism in my model.

3.4.2 Role of Financial Frictions

The model contains four sources of financial frictions. First, firms only have access to state-uncontingent debt to finance operations. Otherwise, firms would be able to allocate assets across states, repay less in bad states, and never default. Second, firms can default on their debts, and the debt prices reflect firms' default probabilities. Third, negative external equity payouts are not allowed, i.e., firms cannot use equity issuance to get rid of financial constraint. Fourth, firms are subject to agency frictions, so they cannot build up a savings buffer to grow out of default risks.

To understand the role of financial frictions in the model, I shut down all the financial incompleteness in a reference model. In this case, the financial market is complete with state-contingent assets and perfect enforcement of debts. Firms are not subject to the non-negative equity payout constraint. The monitor is perfect, so there is no agency problem. This model without financial frictions resembles [Schaal \(2017\)](#), who studies the effect of volatility shocks on unemployment under search and matching frictions.

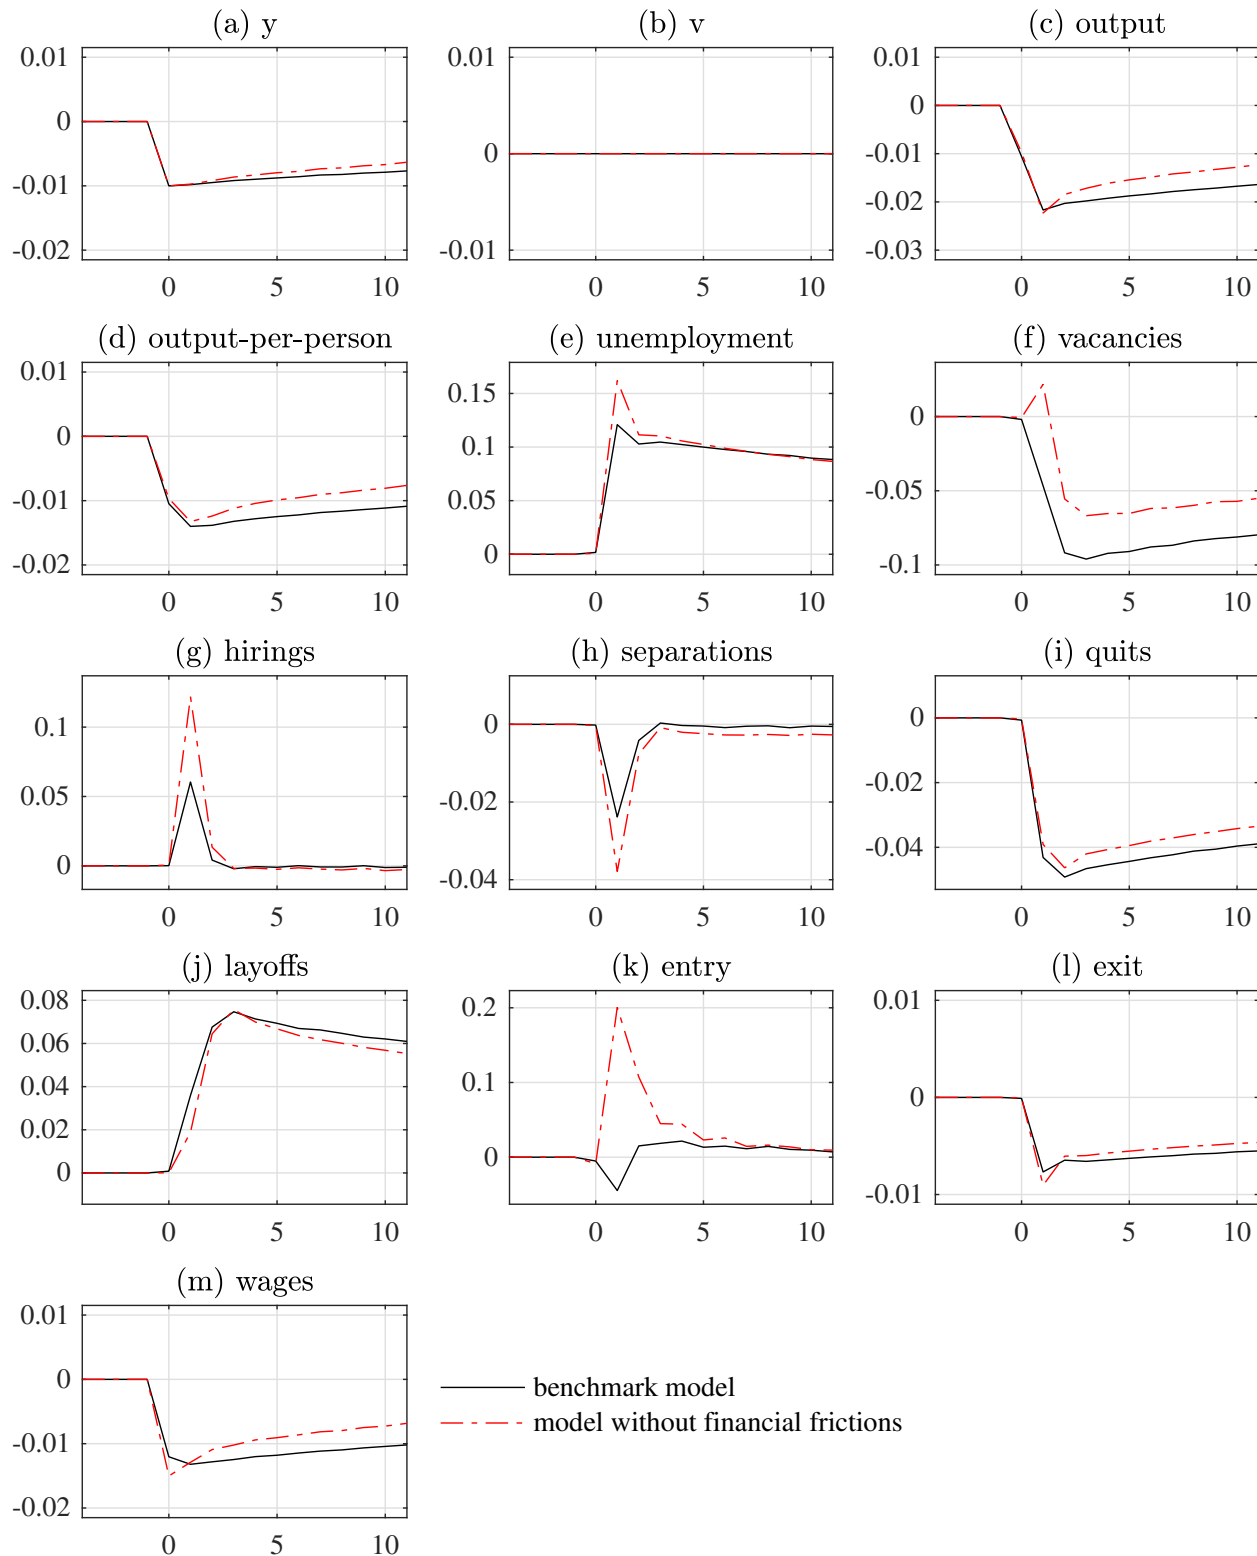

I recalibrate the model to match the targeted moments except for the financial variables. Columns "No Financial Frictions, $A + \sigma$ " of Table 2 and Table 5 show the results of the moment matching and the values of parameters, respectively. Because there are no financial variables to pin down the standard deviation of operating costs, I use the same σ_ϵ as in the benchmark. Financial parameters, including the agency friction $\tilde{\zeta}$, auditing quality ξ , and recovery rate η , are not applicable in this case.

The recalibrated parameters in Table 5 suggest that the standard deviations of both shocks need to increase to match the variations of aggregate output and IQR in the data, in particular the standard deviation of aggregate productivity shocks. The need for larger standard deviations of shocks for the model without financial frictions suggests that financial frictions amplify the effect of shocks.

I use the impulse responses in Figures 3 and 4 to illustrate how financial frictions affect aggregate outcomes.

A Negative Aggregate Productivity Shock. Figure 3 plots the impulse responses to a negative aggregate productivity shock. To draw the impulse responses, I simulate the economy's distribution 4,000 times with stochastic aggregate shocks. At quarter 0, I impose a 1% negative aggregate productivity shock. Then I let the economy evolve stochastically again. The impulse responses in Figure 3 are the average of the 4,000 simulated paths. The solid black lines are from the benchmark

Figure 3: Aggregate Impulse Responses to a 1% Negative Aggregate Productivity Shock

Notes: The panels are impulse responses to a 1% transitory negative aggregate productivity shock at quarter 0. The impulse responses are the average of 4,000 simulated paths, presented as log deviations from the mean. Solid black lines are the benchmark results. Dash-dot red lines are for the model without financial frictions. I use [Schaal's \(2017\)](#) code when plotting.

Figure 4: Aggregate Impulse Responses to a 5% Positive Volatility Shock

Notes: The panels are impulse responses to a 5% positive volatility shock at quarter 0. The impulse responses are the average of 4,000 simulated paths, presented as log deviations from the mean. Solid black lines are the benchmark results. Dash-dot red lines are for the model without financial frictions. I use [Schaal's \(2017\)](#) code when plotting.

model, and the dash-dot red lines are without financial frictions.

For the benchmark model in solid black lines, a 1% negative aggregate productivity shock leads to a 2% decline in output and 10% higher unemployment.

The dash-dot red lines show the results when there are no financial frictions, showing that the changes in output and unemployment are similar to in the benchmark. This finding implies that the financial channel primarily operates through volatility shocks. The reason is that wages decline more with financial frictions (Panel (m)), which offsets the negative impact of lower aggregate productivity.

A Positive Volatility Shock. Figure 4 displays the impulse responses following a 5% positive volatility shock. The methodology to draw the impulse responses is the same, except I shock the simulations with a 5% positive volatility shock at quarter 0.

In the benchmark model, a 5% positive volatility shock lowers output slightly and raises unemployment by 15%, while the model without financial frictions generates an output boom and much less of an increase in unemployment. This result explains why [Schaal \(2017\)](#) finds it difficult for a search model to generate a sufficient increase in unemployment during the Great Recession. In his model, the effect of volatility on unemployment is mainly through the reallocation of workers across firms. My work builds on his by incorporating a financial channel of wage commitments into the model, which interacts with volatility shocks and improves the model's ability to explain unemployment fluctuations.

3.4.3 Role of Volatility Shocks

Recall that Table 3 shows that with only the aggregate productivity shock, the standard deviation of unemployment is significantly smaller. In this section, I explain why the financial channel of wage commitments is particularly influential when interacting with volatility shocks instead of aggregate productivity shocks.

In the last panels of Figures 3 and 4, I show the impulse responses of wages. The decline of wages is much larger in response to a negative aggregate productivity shock than a volatility shock.¹⁷ Because the lower wages offset the effect of the negative aggregate productivity shock, the financial channel of wage commitments does not amplify unemployment volatility much. The offsetting equilibrium effect of wages is also the reason for the unemployment volatility puzzle in [Shimer \(2005\)](#). He finds that the calibrated standard Diamond-Mortensen-Pissarides model generates less than 10% of the observed standard deviation of unemployment. In that model, because of the free entry condition, the decline in wages largely absorbs the effect of aggregate productivity shocks.

¹⁷ Actually, both the wages of incumbent workers and newly hired workers increase when volatility increases. The average wage in Figure 4 decreases because the share of newly hired workers increases, who have lower wages.

Similarly, the free entry condition in my model also leads to a large decrease in wages to offset the impact of aggregate productivity shocks.

Nonetheless, the offsetting effect of wage dynamics is smaller for volatility shocks. The reason why wages do not decrease much is due to a property of volatility shocks. A positive volatility shock spreads the distribution of firm-level productivity. Since a firm's profit is convex in terms of its idiosyncratic productivity, a wider distribution delivers a higher expected profit. The volatility literature calls this property the Oi-Hartman-Abel effect (Oi (1961), Hartman (1972), Abel (1983)). The Oi-Hartman-Abel effect is stronger for firms with high productivity because firm productivity is persistent. These firms' high expected values means that wages do not need to decrease much to satisfy the free entry condition. Since the equilibrium wage is not low enough for a median firm to offset the higher risk of drawing low idiosyncratic productivity, it hires less. At the aggregate level, unemployment increases.

Therefore, the financial channel of wage commitment needs to interact with volatility shocks to improve the model's prediction of unemployment volatility significantly. This finding provides a new way to understand the fluctuations of unemployment. Unlike a typical search model with only aggregate productivity shocks and homogeneous firms, I argue that volatility shocks are crucial to understanding unemployment because firms have limited ability to hedge idiosyncratic risks.

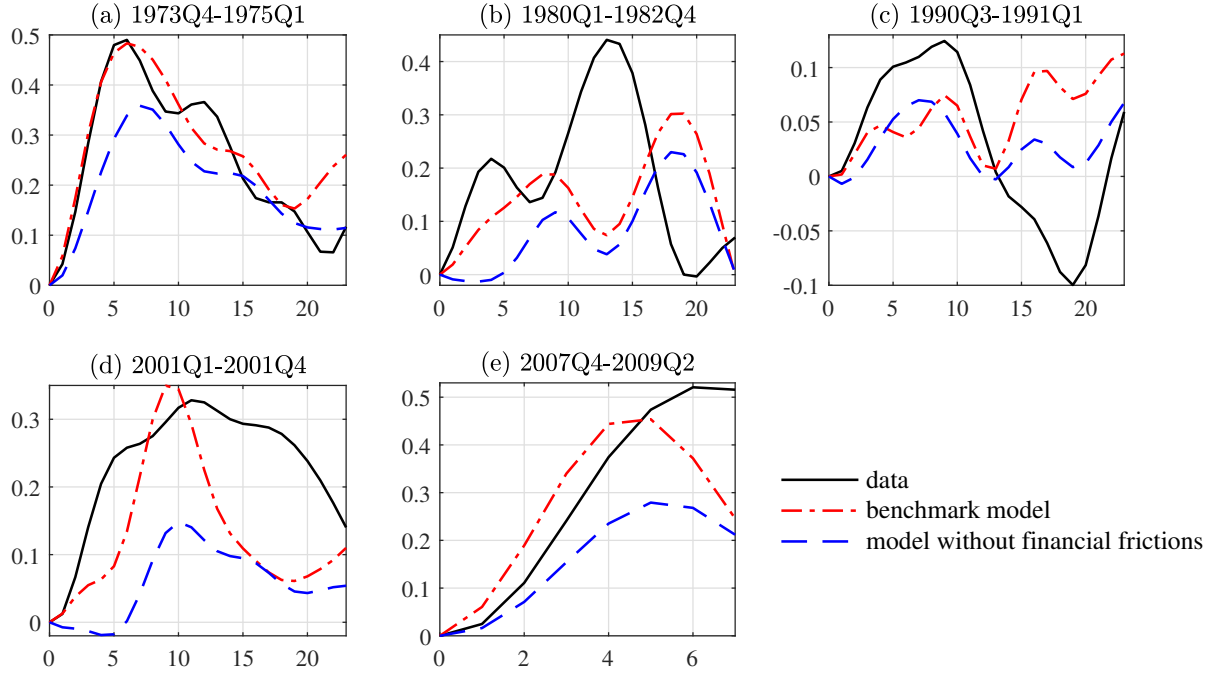

3.5 Event Study for US Recessions

The preceding section shows how my model can generate most of the standard deviation of unemployment in the data. In this section, I apply my model to U.S. recessions in particular.

To leverage the tools of time series analysis, I first obtain the model's state-space mapping between state variables and simulated observables in the spirit of Krusell and Smith (1998). State variables of the state-space model include log aggregate productivity A and log volatility v up to five-quarter lags. I project the aggregate variables of interest on the state variables to get a mapping between observables and states. The aggregate variables include aggregate output, the interquartile range of firm sales growth (IQR), and unemployment. The R^2 of the mapping between the state variables and output, IQR, and unemployment are 0.99, 0.96, and 0.97, respectively. The high R^2 indicates that the state variables can forecast the observables well. Namely, the state-space mapping successfully captures the relation between the underlying shocks and observables, which facilitates estimating the shocks from data in the next step.

To estimate the underlying aggregate productivity shocks and volatility shocks over U.S. business cycles, I apply a Kalman filter to U.S. data. Following Schaal (2017), I use band-pass filtered log real GDP per capita and IQR to jointly smooth out the underlying shocks. This delivers the series

Figure 5: Unemployment Series With and Without Modeling Financial Frictions

Notes: The panels show the model's predictions for unemployment during recessions. I jointly estimate the time series of aggregate productivity shocks and volatility shocks by matching output and the IQR of firm sales growth in the data. The data are detrended by a band-pass filter to focus on fluctuations between 6 and 32 quarters, following [Schaal \(2017\)](#). Given the estimated shocks, I show the model-predicted unemployment. The data on unemployment is the solid black lines. The unemployment fluctuations predicted by the benchmark model are the dash-dotted red lines, and model unemployment without financial frictions is the dashed blue line. Consistent with [Schaal \(2017\)](#), series are depicted in terms of log deviations from the peak preceding the recession. I use [Schaal's \(2017\)](#) code when plotting.

of estimated shocks $\{\hat{\epsilon}_t^A, \hat{\epsilon}_t^\sigma\}$. Next, given the estimated shocks, the model predicts unemployment.

Figure 5 shows the peak-to-trough log deviations of unemployment in recessions since 1973. The black lines are the data and the dash-dotted red lines are the predictions of the benchmark model. The benchmark model can explain a great share of the increase in unemployment during recessions.

To understand the role of financial frictions, I also show the predictions of the counterfactual model without financial frictions using dashed blue lines. In line with the business cycle statistics in Table 3, the model without financial frictions generates less of an increase in unemployment during recessions. Moreover, the prediction for the Great Recession particularly deteriorates.

Table 4 reports the peak-to-trough changes in output and unemployment during recessions. Because I estimate the underlying shocks by matching output, both the benchmark model and the model without financial frictions have similar output declines as in the data. On the other hand, adding financial frictions improves the model's ability to generate elevated unemployment in recessions. In particular, consider the Great Recession, where unemployment increased by 50%.

Table 4: Peak-To-Trough Changes During Recessions

	1973-1975	1980-1982	1990-1991	2001	2007-2009
<i>Output</i>					
Data	-0.082	-0.069	-0.021	-0.038	-0.048
Benchmark model	-0.082	-0.069	-0.021	-0.038	-0.049
Model without financial frictions	-0.082	-0.068	-0.021	-0.037	-0.052
<i>Unemployment</i>					
Data	0.490	0.441	0.124	0.328	0.521
Benchmark model	0.502	0.308	0.109	0.352	0.457
Model without financial frictions	0.389	0.240	0.064	0.143	0.282

Notes: The table shows the peak-to-trough changes in output and unemployment during recessions for both the data and models. I jointly estimate the time series of aggregate productivity shocks and volatility shocks by matching output and the IQR of firm sales growth in the data. The data are detrended by a band-pass filter to focus on fluctuations between 6 and 32 quarters, following [Schaal \(2017\)](#). Given the estimated shocks, I show the peak-to-trough changes predicted by the model during recessions. Consistent with [Schaal \(2017\)](#), series are depicted in terms of log deviations from the peak preceding the recession.

The model without financial frictions can only explain about half of this rise, while the benchmark model can generate 90% of the increase in unemployment.

My result builds on [Schaal \(2017\)](#), who finds that a search model cannot replicate unemployment during the Great Recession. He also conjectures that adding financial frictions is a possible way to improve the model's performance. My model confirms that adding financial frictions does go a long way to make the model better account for the Great Recession.

3.6 Policy Implications

Given the quantitative performance of my model, I apply it to the labor market policies of the U.S. and Germany during the recent Covid recession. I also discuss how the measured effects of these policies are biased when financial frictions are not considered.

U.S. Policy. In the recent 2020 Covid-19 pandemic, the U.S. market uncertainty increased dramatically. Specifically, [Altig et al. \(2020\)](#) show that business executives are much more uncertain about their firms' future sales growth rates during the COVID-19 pandemic, according to the U.S. monthly panel Survey of Business Uncertainty (SBU) and the U.K. monthly Decision Maker Panel (DMP). At the same time, the U.S. government deployed economic support policies. One notable response was the U.S. Federal Pandemic Unemployment Compensation (FPUC) program, which increased unemployment benefits by an extra \$600 per week.

To figure out the aggregate impacts of this policy, I modify my model to incorporate this policy and re-solve it quantitatively. Specifically, I model that the government increases unemployment benefits by 1% when volatility is high. And the policy is anticipated by all agents. For simplicity,

Figure 6: Policy Implications of a Transitory Positive Volatility Shock

Panel A: Benchmark Model

Panel B: Model Without Financial Frictions

Notes: The panels are impulse responses to a 5% positive volatility shock at quarter 0. The impulse responses are the average of 4,000 simulated paths, presented as log deviations from the mean. Solid black lines are the benchmark results. Dash-dot red lines are for the model with enhanced U.S. unemployment benefits. Dashed blue lines are for the model with German wage subsidies. I use [Schaal's \(2017\)](#) code when plotting.

I assume that the government collects tax revenue through a lump-sum tax, and this policy costs about 4.8 basis points of output in the simulation.

As Figure 4, Panel A of Figure 6 shows the impulse responses to a 5% positive volatility shock. The solid black lines are the results of the benchmark model as Figure 4, and the dashed red lines are for the model with the U.S. policy, which raises unemployment benefits by 1% when the volatility shock hits. It turns out that this policy amplifies the recession by generating lower output and higher unemployment. The reason is that increased unemployment utility distorts the labor

market by pushing up wages, which not only increases the cost of production but also strengthens the financial concern of wage payments. Therefore, the recession is deepened.

German Policy. Germany has a very different social security system from the U.S. In Germany's social insurance program, *Kurzarbeit*, when firms cut workers' hours, the government pays the lost earnings to workers. In other words, the government helps firms to pay wages when there is a bad shock.¹⁸ I model Germany's policy by allowing the firm to have an option to let part of its workforce idle when volatility is high, and the government pays 84.4% of the idle workers' wages while the firm pays the rest. This replacement rate is chosen to have the same 4.8 basis points government expenditure to output ratio as the U.S. The dash-dot blue lines in Figure 6 are the impulse responses of a transitory positive volatility shock under Germany's policy. The impulse responses almost do not change because the following channels have offsetting effects. On one hand, this policy can avoid temporary unemployment and reduce search costs when the shock is transitory, dampening the recession. Moreover, the policy provides state-contingent insurance to firms to help them pay wages. Since the financial channel of wage commitments is weakened, this effect is also beneficial.

On the other hand, two effects are offsetting the benefits. First, this policy is costly for firms to apply for. Notice that workers do not work when their wages are subsidized by the government. The loss of output hinders firms from benefiting from this policy. Second, this policy induces firms to hire more workers in advance, which can cause a massive layoff after the shock hits. Both of these effects amplify the recession.

Biased Policy Evaluation Without Consideration of Financial Frictions. I have already shown that financial frictions are crucial for my model's implications for business cycles. Another question is how important financial frictions are for policy evaluation. To answer this question, I apply the above two policy experiments to the recalibrated model without financial frictions. Panel B of Figure 6 shows the results.

Germany's policy still has mild effects for similar reasons. However, the negative impact of the U.S. policy is greatly underestimated when financial frictions are ignored. In the benchmark model, the U.S. policy causes a larger decrease in output and increase in unemployment. The reason is that this policy pushes up wages, making firms more concerned about the financial burden of wage payments and leading them to reduce hiring commitments in the benchmark model. But the model without financial frictions does not consider this effect. Therefore, without considering financial frictions, the negative impact of increasing unemployment benefits is undermined.

To sum up, the U.S. policy pays unemployed workers more during high volatility states, making it more expensive for firms to pay wages; Germany's policy provides firms with wage subsidies when they cannot afford to retain workers, which helps firms keep workers when facing shocks.

¹⁸ Cooper, Meyer and Schott (2017) provides information on this system.

My quantitative results show that German policy has mild impacts and U.S. policy amplifies recessions. The negative effects of the U.S. policy are underestimated when the financial channel is omitted. It is worth noting that my model does not have any demand effects, which can potentially increase the benefits of the two policies and limits the accuracy of this model exercise.

4 Conclusion

This paper uses a novel model to study the financial effect of wage commitments on unemployment in the presence of volatility shocks. When volatility rises, firms are less likely to make wage commitments, so labor demand decreases and unemployment increases.

The model builds on [Schaal \(2017\)](#) by generating more unemployment volatility and a larger increase in unemployment during the Great Recession. This result is driven by the interaction between volatility shocks and the financial channel of wage commitment. The key is that firms have limited ability to hedge the risks of idiosyncratic productivity variations.

With rich micro-foundations and realistic quantitative performance, my model has potential for wide application. As an example, I use this framework to investigate labor market policies. I find that raising unemployment benefits as the United States did during the Covid recession amplified the recession. On the other hand, a German approach of subsidizing firm wage bills has little impact.

Notes: The first column shows the calibrated parameters of the benchmark model. The other columns report the recalibrated parameters for reference models. $A + \sigma$ means the model has both aggregate productivity shocks and volatility shocks, and A means the model only has aggregate productivity shocks.

Appendix B Figures

Figure 7: Output Series With and Without Modeling Financial Frictions

Notes: The panels show the model's predictions for output during recessions. I jointly estimate the time series of aggregate productivity shocks and volatility shocks by matching output and the IQR of firms' sales growth in the data. The data are detrended by a band-pass filter to focus on fluctuations between 6 and 32 quarters, following [Schaal \(2017\)](#). Given the estimated shocks, I show the model-predicted output. The data on output is the solid black lines. The output fluctuations predicted by the benchmark model are the dash-dotted red lines. The output of the model without financial frictions is the dashed blue line. Consistent with [Schaal \(2017\)](#), series are depicted in terms of log deviations from the peak preceding the recession. I use [Schaal's \(2017\)](#) code when plotting.

Figure 8: Comparison of Imputed Shocks with [Schaal \(2017\)](#)

Notes: This figure compares the imputed aggregate productivity shocks and volatility shocks with [Schaal \(2017\)](#). The shocks are estimated to match the data series of output and the IQR of firm sales growth. The black lines in Panel A show the log deviations of aggregate productivity and volatility of the benchmark model. The blue lines in Panel B are the results of the model without financial frictions. The red dashed lines in both panels are the results of [Schaal \(2017\)](#).

Appendix C Proofs

Proposition 1 *The participation constraint binds, i.e., $\bar{W}(i') = 0$, for any worker i' .*

Proof I prove this proposition by contradiction. Suppose $\exists i'$ such that $\bar{W}(i') > 0$ in the optimal policy. The firm can construct an alternative policy with $\bar{W}(i') = 0$ and achieves a higher value. The main idea of the alternative policy is to frontload wages and borrow more.

Case 1. Suppose i' is an incumbent worker. Recall that the promise-keeping constraint always binds in the optimal policy. Construct an alternative policy by letting $\bar{W}(i')$ decrease to zero and increase the next-period wage of worker i' to satisfy tomorrow's binding promise-keeping constraint. Use δ to denote the decrease of tomorrow's wage bill $\int_0^{n'} w(i') di'$. At the same time, increase b' by δ so that next-period cash on hand is the same. Thus, the next-period default decisions are unchanged, and so is the expected value of the firm in the next period. The agency friction constraint (11) holds as well. On its left-hand side, borrowing increases, while the right-hand side decreases because of lower next-period wage bills.

Next, I prove that current equity payouts increase as follows. Because the future promised utility decreases, the worker's current wage should increase accordingly to satisfy today's promise-keeping constraint. To see how much the wage needs to increase, rewrite the worker's problem (2) as:

$$\begin{aligned} W(S, s, C) = \max_x w + \beta \mathbb{E} \Big[& [\tau + (1 - \tau)(\pi_d + (1 - \pi_d)d(S', s'))]U(S') \\ & + (1 - \tau)(1 - \pi_d)(1 - d(S', s'))[U(S') + \bar{W}(i')] \Big] \\ & + \lambda p(\theta(S, x)) \Big[x - \beta \mathbb{E} \Big[[\tau + (1 - \tau)(\pi_d + (1 - \pi_d)d(S', s'))]U(S') \\ & + (1 - \tau)(1 - \pi_d)(1 - d(S', s'))[U(S') + \bar{W}(i')] \Big] \Big]. \end{aligned} \quad (52)$$

Because the last term increases when $\bar{W}(i')$ decreases, the firm's current wage bill only needs to increase by less than $(1 - \tau)(1 - \pi_d)\beta \mathbb{E}[(1 - d(S', s'))]\delta$ to satisfy the same employment value W .¹⁹

Recall that b' increases by δ , and the default probability is unaffected, so the change in current equity payouts is:

$$\begin{aligned} \Delta^{\text{new}} - \Delta^{\text{old}} & \geq Q(S, z, b' + \delta, n)(b' + \delta) - Q(S, z, b', n)b' - (1 - \tau)(1 - \pi_d)\beta \mathbb{E}[(1 - d(S', s'))]\delta \\ & = \beta \mathbb{E}_{S', z' | S, z} \left\{ (1 - \pi_d)\Phi(\bar{\epsilon}(S', z', b', n')) \right\} (b' + \delta) - \beta \mathbb{E}_{S', z' | S, z} \left\{ (1 - \pi_d)\Phi(\bar{\epsilon}(S', z', b', n')) \right\} b' \\ & \quad + \beta \mathbb{E}_{S', z' | S, z} \left\{ [1 - (1 - \pi_d)\Phi(\bar{\epsilon}(S', z', b', n'))] \min \left\{ \eta \frac{A' z' n'^\alpha - (\int_0^{n'} w(i') di' - \delta) - \bar{w}_m - \mu_\epsilon}{b' + \delta}, 1 \right\} \right\} (b' + \delta) \end{aligned}$$

¹⁹ Notice that when the future promised utility decreases, the worker will do more on-the-job search, which allows the firm to lower the wage.

$$\begin{aligned}
& -\beta \mathbb{E}_{S',z'|S,z} \left\{ [1 - (1 - \pi_d)\Phi(\bar{\epsilon}(S',z',b',n'))] \min\left\{ \eta \frac{A'z'n'^\alpha - \int_0^{n'} w(i')di' - \bar{w}_m - \mu_\epsilon}{b'}, 1 \right\} \right\} b' \\
& - (1 - \tau)(1 - \pi_d)\beta \mathbb{E}[(1 - d(S',s'))]\delta \\
& = \beta \mathbb{E}_{S',z'|S,z} \left\{ (1 - \pi_d)\Phi(\bar{\epsilon}(S',z',b',n')) \right\} \delta \\
& + \beta \mathbb{E}_{S',z'|S,z} \left\{ [1 - (1 - \pi_d)\Phi(\bar{\epsilon}(S',z',b',n'))] \min\left\{ \eta A'z'n'^\alpha - \left(\int_0^{n'} w(i')di' - \delta \right) - \bar{w}_m - \mu_\epsilon, b' + \delta \right\} \right\} \\
& - \beta \mathbb{E}_{S',z'|S,z} \left\{ [1 - (1 - \pi_d)\Phi(\bar{\epsilon}(S',z',b',n'))] \min\left\{ \eta A'z'n'^\alpha - \int_0^{n'} w(i')di' - \bar{w}_m - \mu_\epsilon, b' \right\} \right\} \\
& - (1 - \tau)(1 - \pi_d)\beta \mathbb{E}[(1 - d(S',s'))]\delta \\
& \geq \beta \mathbb{E}_{S',z'|S,z} \left\{ (1 - \pi_d)\Phi(\bar{\epsilon}(S',z',b',n')) \right\} \delta - (1 - \tau)(1 - \pi_d)\beta \mathbb{E}[(1 - d(S',s'))]\delta \\
& \geq 0.
\end{aligned}$$

Case 2. Suppose i' is a newly hired worker. As before, construct an alternative policy by letting $\bar{W}(i') = 0$. Accordingly, increase the worker's wage in the next period and increase borrowing so that the firm's expected value does not change. The agency friction constraint holds as before. Next, lower the current wages of new hires $\int_{n'-n_h}^{n'} w_h(i')di'$ by less than $(1 - \tau)(1 - \pi_d)\beta \mathbb{E}[(1 - d(S',s'))]\delta$. Because borrowing increases by more than wages, current equity payouts increase.

Therefore, the alternative policy is feasible and better, so any policy with a loose participation constraint is not optimal. \square

Appendix D Micro-Foundations of Incomplete Labor Contracts

In this section, I use asymmetric information between the firm and its employees to show that the promised utility markup \bar{W} is state-uncontingent. The key assumption is that firms know the realized shocks immediately, but employees know the shocks later in the production stage. This information friction explains why labor contracts are not completely state-contingent, i.e., constraint (7). The logic follows [Hall and Lazear \(1984\)](#). They use asymmetric information to justify the optimality of pre-determined wages. We share the mechanism that firms can lie about the states, so the only incentive-compatible result is state-uncontingent promises. I will first set up the model with asymmetric information and then prove the optimality of state un-contingency.

On top of the timeline in Figure 1, Figure 9 adds the timing for asymmetric information. When shocks (S, s) realize at the beginning of each period, firms know the shocks, but workers do not. If a worker leaves the firm now, he is unemployed and obtains the unemployment value in the current period. Given the shocks, firms choose to exit or stay. Staying firms declare their current shocks are \tilde{S} and \tilde{s} and update contracts. Notice that the declaration can differ from the true state since workers do not observe the information now. I allow the declarations to differ across the firm's employees. Given that the labor contract has been updated, the worker gets nothing in the current period if he leaves the firm now.²⁰ At the production stage, the shocks (S, s) become public information. Workers receive wage payments according to the labor contract, which depends on the firm's declaration of the state (\tilde{S}, \tilde{s}) . At the end of the period, firms separate, search, and match.

The labor contract C contains $\{w, \tau, \bar{W}(S', s'), d(S', s')\}$. Notice I assume that the contract directly specifies the markup $\bar{W}(S', s')$ between the lifetime promised utility $W'(S', s')$ and the outside value of unemployment $U(S')$, which facilitates proving the markup's state-uncontingency.²¹

²⁰ This assumption facilitates the proof because workers have no incentive to threaten to leave the firm (Proposition 2(i).)

²¹ In the traditional implicit contract literature, the labor contract specifies the lifetime utility. Instead, I assume that the contract specifies the promised utility markup in this paper, which is a weaker assumption in my context. Specifically, by asymmetric information, I will prove that the promised value in the contract is state-uncontingent. When the contract specifies the promised utility markup, it implies only the markup part is state-uncontingent, and the promised lifetime utility can still vary with aggregate states, similar to a standard Diamond-Mortensen-Pissarides search model. If the contract specifies the lifetime utility, then the whole lifetime utility is state-uncontingent, implying greater rigidity. This is a stronger assumption than is unnecessary for my model.

Figure 9: Timing With Asymmetric Information

Given the labor contract, the worker's employment value is:

$$\begin{aligned}
 W(S, s, C) = & \max_x w + \lambda p(\theta(S, x))x + (1 - \lambda p(\theta(S, x)))\tau\beta \mathbb{E}_{S'|S} U(S') \\
 & + (1 - \lambda p(\theta(S, x)))(1 - \tau)\beta \max \left\{ \underbrace{\mathbb{E}_{S'|S} U(S')}_{\text{leave before the contract is updated}}, \mathbb{E}_{S', s'|S, s} \{(\pi_d + (1 - \pi_d)d(S', s'))U(S')\} \right\} \\
 & + (1 - \pi_d)(1 - d(S', s')) \max \{ U(S') + \bar{W}(\tilde{S}^*, \tilde{s}^*), \underbrace{0 + \beta \mathbb{E}_{S''|S'} U(S'')}_{\text{leave after the contract is updated}} \} \}.
 \end{aligned} \tag{53}$$

As before, the worker receives the wage w at the production stage. The worker can conduct on-the-job search and leave the firm. If the worker stays but gets laid off, he will be unemployed in the next period and receive the unemployment value $U(S')$.

If the worker is not laid off, he can still leave the firm when the outside value is high enough. But the outside value depends on the timing of leaving the firm. If the worker leaves the firm before the contract is renewed, he is counted as unemployed and receives the unemployment value just like a laid-off worker. However, if he leaves the firm after the contract is renewed, he receives zero and gets the unemployment value one period later. This setup can be understood as the worker being ineligible to receive unemployment benefits after the labor relation renews, and drawing up contracts is time-consuming, so he does not have time to produce at home in the same period. Hence, the utility is zero in that period. This assumption will imply that workers have no incentive to threaten to quit when they find the firm lies (Proposition 2(i)), facilitating the proof.

If the labor relation persists, the worker will receive the lifetime utility $U(S') + \bar{W}(\tilde{S}^*, \tilde{s}^*)$. Notice that because of asymmetric information, the realized promised utility markup \bar{W} depends on the firm's declaration of shocks $(\tilde{S}^*, \tilde{s}^*)$. To clarify, $\{\bar{W}(S', s')\}$ in the labor contract is the set of utility markups for the next period. However, how much the worker can get in the next period depends on the firm's optimal declaration of shocks $(\tilde{S}^*, \tilde{s}^*; i)$.

A firm's states include realized aggregate shocks $S \in \mathcal{S}$, realized firm-specific shocks $s \in \mathcal{s}$, the number of employees n , and the set of promised utility markups to its employees $\{\bar{W}(S, s; i)\}_{S \in \mathcal{S}, s \in \mathcal{s}; i \in [0, n]}$, where i is the index of incumbent employees within the firm. In a slight abuse of notation, S and s inside $\bar{W}(\cdot, \cdot; i)$ refer to the possible shocks instead of the realized shocks.

Besides the choice variables in the original firm's problem (3), the firm now also chooses to declare the current shocks, $\tilde{S}(i)$ and $\tilde{s}(i)$, to each employee i . The following equations (54) to (60) summarize the firm's problem:

$$\begin{aligned} J(S, s, b, n, \{\bar{W}(S, s; i)\}_{S \in \mathcal{S}, s \in \mathcal{s}; i \in [0, n]}) = & \max_{\substack{\Delta, b', n', n_h, x_h, d(S', s') \\ \{\tilde{S}(i), \tilde{s}(i), w(i), \tau(i)\}_{i \in [0, n]}, \\ \{w_h(i')\}_{i' \in (n' - n_h, n']}, \\ \{\bar{W}(S', s'; i')\}_{S' \in \mathcal{S}', s' \in \mathcal{s}'; i' \in [0, n']}}} \Delta \end{aligned} \quad (54)$$

$$+ \beta(1 - \pi_d) \mathbb{E}_{S', s' | S, s} \left\{ (1 - d(S', s')) J(S', s', b', n', \{\bar{W}(S', s'; i')\}_{S' \in \mathcal{S}', s' \in \mathcal{s}'; i' \in [0, n']}) \right\} \quad (55)$$

s.t. (4), (5), (6), (10), (11),

$$\begin{aligned} W^E(i') \equiv \mathbb{E}_{S', s' | S, s} \{ & (\pi_d + (1 - \pi_d)d(S', s'))U(S') \\ & + (1 - \pi_d)(1 - d(S', s')) \max\{U(S') + \bar{W}(\tilde{S}^*, \tilde{s}^*; i'), 0 + \beta \mathbb{E}_{S'' | S'} U(S'')\} \}, \end{aligned} \quad (56)$$

$$W^E(i') \geq \mathbb{E}_{S' | S} U(S'), \forall i' \in [0, n'], \quad (57)$$

$$\max_x w(i) + \lambda p(\theta(S, x))x + (1 - \lambda p(\theta(S, x)))\tau(i)\beta \mathbb{E}_{S' | S} U(S') \quad (58)$$

$$+ (1 - \lambda p(\theta(S, x)))(1 - \tau(i))\beta W^E(i') \geq U(S) + \bar{W}(\tilde{S}, \tilde{s}; i), \text{ for } i' \in [0, n' - n_h], \quad (59)$$

$$w_h(i') + \beta W^E(i') \geq x_h, \text{ for } i' \in (n' - n_h, n']. \quad (60)$$

Equations (56) to (60) describe the new implicit contract constraints in the presence of asymmetric information. First, equation (56) uses W^E to denote the worker's expected lifetime utility if he stays with the firm. Notice that W^E is also the last part of the employment value (53). Constraint (57) is the new participation constraint, meaning that the worker's expected utility is at least the expected unemployment value so that he will stay. Equation (58) is the new promise-keeping constraint for incumbent workers. This constraint requires the firm to commit to paying the employee at least the promised lifetime utility. The left-hand side is the incumbent worker's employment value, i.e., equation (53). The right-hand side is the promised lifetime utility, comprised of two parts—the unemployment value $U(S)$ and the promised utility markup $\bar{W}(\tilde{S}, \tilde{s}; i)$. Notice that $\tilde{S}(i)$ and $\tilde{s}(i)$ are the firm's declarations of shocks, two of the firm's choice variables. They can be different from the true shocks because firms know the realized shocks when renewing labor contracts, but workers do not. The declarations can be different across the firm's employees. Equation (60) is the new promise-keeping constraint for newly hired workers. Its left-hand side is the newly hired

worker's employment value. On the right-hand side, x_h is the submarket where the firm employs new workers, and x_h is also the promised lifetime utility of the vacancies posted in that submarket. Thus, equation (60) means the firm should guarantee that newly hired workers receive at least the lifetime utility promised by the offer.

The following Proposition 2 proves that the promised utility markup \bar{W} is state-uncontingent.

Proposition 2 *The labor relation between the firm and its employees has the following properties:*

- (i) *Workers do not leave the firm even if they find the firm lied.*
- (ii) *The promised utility markup \bar{W} is state-uncontingent.*

Proof As for point (i), recall that employees discover whether the firm lied about shocks in the production stage. If they leave the firm now, they get nothing today and start receiving the unemployment value in the next period. So, even if the firm gives the worker zero wages and fires them right after the production stage, the worker is willing to stay with the firm.

As for point (ii), because employees will not leave the firm regardless, according to point (i), lying about the shocks has no consequences for the firm. Thus, firms always declare the lowest employment surplus in $\{\bar{W}(S, s; i)\}_{S \in S, s \in s}$ to each employee i . Therefore, the incentive-compatible labor contract requires the promised utility markup \bar{W} to be state-uncontingent. \square
